(Dated: August 28, 2015)

We study the electron as a system composed by an electron and a photon, using lowest order perturbation theory. We derive the leading-twist transverse-momentum-dependent distribution functions for both the electron and photon in the dressed electron, thereby offering a three-dimensional description of the dressed electron in momentum space. To obtain the distribution functions, we apply both the formalism of light-front wave function overlap representation and the diagrammatic approach. We perform the calculations both in light-cone gauge and Feynman gauge, and we present a detailed discussion of the role of the Wilson lines to obtain gauge-independent results. We provide numerical results and plots for many of the computed distributions.

I. INTRODUCTION

The electron is an elementary field of Quantum ElectroDynamics (QED) and, as such, is a structureless object. When we study the electron “structure”, what we are in fact doing is probing the quantum fluctuations of the theory. Due to Heisenberg uncertainty principle, the electron can fluctuate into a virtual electron-photon pair, carrying the same quantum number of the electron, i.e. $e \rightarrow e\gamma \rightarrow e$. The virtual photons can themselves break up into pairs of virtual electrons and positrons and, as a result, an isolated electron is in reality surrounded by a composite virtual cloud of photons, electrons, and positrons in all possible combinations, consistently with the quantum number of the electron. Therefore, the “bare” electron effectively becomes a “dressed” electron. Photons, electrons, and positrons can be interpreted in this case as partons contained in the original electron, in analogy to the partonic structure of hadrons.

If one of the virtual states of the electron cloud interacts with a probe, the parton content of the electron is resolved and the electron reveals its structure. Such behavior is an important aspect of quantum field theories, and similar phenomena arise in many different situations. For example, in QCD, the quark splitting to quarks and gluons drives the scaling violations in hadronic structure functions [1]. Analogously, the QED radiative corrections to the electron can be recast in the formalism of structure functions (see, e.g., [2, 3]). Other possible descriptions of the parton structure of the electron can be obtained in analogy to the QCD formalism of parton correlation functions, which can be parametrized in terms of different types of distribution functions (see, e.g., [4–6]) known as generalized transverse-momentum dependent parton distributions (GTMDs), generalized parton distributions (GPDs), transverse momentum dependent parton distributions (TMDs) and collinear parton distribution functions (PDFs).

These distribution functions allow us to view the dressed electron from a new perspective. For instance, it is possible to introduce the notion of the shape of the electron [7, 8], to analyze how the spin of the electron is split into the spins and orbital angular momenta (OAM) of the partons in the electron’s cloud [9–11], and to compute all possible correlations between spin, momentum and position of the partons. Moreover, the study of QED parton distribution functions can help shedding light on several formal aspects of their QCD analogues.

In this work, we will focus on the study of TMDs, which describe the distribution of QED partons in the dressed electron as a function of their longitudinal and transverse momentum, and therefore give access to the three-dimensional picture of the dressed electron in momentum space. At leading twist there are eight TMDs, for both the active electron and photon, characterizing the strength of different spin-spin and spin-orbit correlations of the partons and electron

target. Three of them survive when integrated over the transverse momentum, giving rise to the familiar collinear PDFs. Formally, the transverse-momentum dependence in the distribution functions arises from the definition in terms of bilocal operator matrix elements off the light-cone. To comply with gauge invariance, one has to introduce non-trivial gauge links, which compensate for the non-locality of the fields [12–16]. The Wilson line accounts for the (infinitely many, in principle) photons that can be absorbed or emitted by the initial or final state, and is the source of interesting phenomena like single spin asymmetries [17, 18].

In a diagrammatic approach, the gauge-link contribution can be studied via a perturbative expansion in the coupling constant. Thanks to its Abelian nature, QED is simpler to deal with compared to QCD, and can therefore serve as a useful testing ground for full perturbative calculations. In this article, we will work in the leading order approximation, corresponding to the exchange of a single gauge boson between the active parton and the spectators. In particular, we will use QED Feynman rules for the eikonal propagator, and we will explicitly show the equivalence of the resulting TMDs in different gauges, namely Feynman and light-cone gauge.

Besides the diagrammatic approach, a useful framework to study parton distributions is the representation in terms of overlap of light-front wave functions (LFWFs) [19]. The LFWFs of the electron corresponding to the minimal Fock state component of an electron-photon pair are computable explicitly from time-ordered perturbation theory in the light-cone gauge. Several applications using the electron LFWFs have been discussed, focusing in particular in the study of the distributions in impact-parameter space as obtained from the GPDs [7, 8, 17, 20–25]. Here we will extend the study with LFWFs to the TMDs, of both the electron and photon partons.

The diagrammatic approach and the LFWFs overlap representation are used as alternative, but equivalent, descriptions to emphasize different aspects of the physical content of the TMDs. The diagrammatic approach allows us to unravel more explicitly the role of gauge invariance in the definition of the TMDs, while the representation in terms of LFWFs, being eigenstates of the parton light-front helicity and OAM in the light-cone gauge, exposes more explicitly the information about the spin-spin and spin-orbit correlations encoded in the TMDs.

The outline of this work is as follows. In Sec. II we set up the general framework for the TMDs of the electron, introducing the definition of the correlator function and discussing the role of the Wilson line in QED. In Sec. III we derive the leading-twist TMDs using the diagrammatic approach in the Feynman gauge, at leading order in α . In Sec. IV we sketch the derivation of the LFWF for the electron-photon Fock state component and discuss the LFWF overlap representation of the TMDs, showing the equivalence of the results within the diagrammatic approach. In Sec. V we study in some detail the role of the transverse components of the Wilson line in the light-cone gauge, using different prescriptions for the regularization of the light-cone singularity from the photon propagator. In Sec. VI we turn our attention to the photon contribution to the dressed-electron TMDs. In Sec. VII, we present the results for the electron and photon TMDs, discussing the role of the spin and parton OAM in shaping the transverse-momentum dependence of the different TMDs. Finally, we conclude with a section summarizing our findings.

II. GENERAL FRAMEWORK

Let us consider a dressed electron of mass m , spin S and 4-momentum P , composed of a bare electron of momentum k and a photon of momentum $P - k$. If we write a generic vector a^μ in light-cone coordinates as $a^\mu = (a^+, a^-, \mathbf{a}_\perp)$, we set the momentum of the inner electron as $k \equiv (xP^+, k^-, \mathbf{k}_\perp)$, with the longitudinal momentum fraction x defined as $x := k^+/P^+$. We begin with the definitions related to the distribution functions of the bare electron; those for the photon will be discussed in Sec. VI. In analogy to the QCD case, if we probe the internal structure of the electron via the scattering of a virtual photon (see Fig. 1), the most general expression for the correlator function between initial and final electron states is given by [4, 26–28]

$$\Phi_{ij}(k; P, S) := \int \frac{d^4\xi}{(2\pi)^4} e^{ik \cdot \xi} \langle P, S | \bar{\psi}_j(0) \psi_i(\xi) | P, S \rangle. \quad (1)$$

In Eq. (1) $\psi(x)$ is the electron field, while the indices i and j refer to Dirac space and will be omitted from now on. If we integrate (1) over k^- , we obtain the transverse-momentum dependent correlator, which enters the definition of the TMDs:

$$\Phi(x, \mathbf{k}_\perp; P, S) = \int dk^- \Phi(k; P, S) = \int \frac{d\xi^- d^2\xi_\perp}{(2\pi)^3} e^{ik \cdot \xi} \langle P, S | \bar{\psi}(0) \psi(\xi) | P, S \rangle \Big|_{\xi^+=0}. \quad (2)$$

FIG. 1: Handbag diagram for the dressed electron in QED at order α (left), separated in its upper and lower part (right), the latter being the diagrammatic representation of the electron-electron correlator Φ .

If we further integrate (2) over \mathbf{k}_\perp , we reduce ourselves to a correlator function that depends only on the longitudinal momentum fraction x , giving access to the collinear PDFs:

$$\Phi(x; P, S) = \int dk^- d^2\mathbf{k}_\perp \Phi(k; P, S) = \int \frac{d\xi^-}{2\pi} e^{ik \cdot \xi} \langle P, S | \bar{\psi}(0) \psi(\xi) | P, S \rangle \Big|_{\xi^+ = \xi_\perp = 0}. \quad (3)$$

From a diagrammatic point of view, the correlator corresponds to the lower part of the handbag diagram in Fig. 1.

In order for the bilocal products of field operators in the correlator functions to be gauge invariant, we have to insert a Wilson line between the two electron fields [12, 13, 27, 29, 30]. Indeed, the QED Lagrangian¹

$$\mathcal{L}_{\text{QED}} = \bar{\psi}(i\cancel{D} - m)\psi - \frac{1}{4}F^{\mu\nu}F_{\mu\nu} + e\bar{\psi}\gamma^\mu\psi A_\mu, \quad (4)$$

where the photon field tensor is $F^{\mu\nu}(\xi) = \partial^\mu A^\nu(\xi) - \partial^\nu A^\mu(\xi)$, is invariant under the following local gauge transformation of the fields:

$$\psi(\xi) \rightarrow e^{ie\alpha(\xi)}\psi(\xi), \quad A^\mu(\xi) \rightarrow A^\mu(\xi) + \partial^\mu\alpha(\xi). \quad (5)$$

However, this transformation does not leave the correlator Φ invariant, since

$$\bar{\psi}(0)\psi(\xi) \rightarrow \bar{\psi}(0)\psi(\xi) e^{-ie[\alpha(0)-\alpha(\xi)]}. \quad (6)$$

The standard way to ensure gauge invariance of the correlator Φ is to insert in our definition a gauge link operator $U_{(0,\xi)}$ connecting the fields evaluated at different points. Let us define, in general [16]:

$$\mathcal{U}_{(\xi_1, \xi_2)} := \exp \left[-ie \int_{\xi_1}^{\xi_2} d\eta^\mu A_\mu(\eta) \right], \quad (7)$$

where the integral is meant to run along any path connecting ξ_1 to ξ_2 . Acting with the gauge transformation (5), the Wilson line will turn into:

$$\mathcal{U}_{(\xi_1, \xi_2)} \rightarrow \exp \left[-ie \int_{\xi_1}^{\xi_2} d\eta^\mu A_\mu(\eta) \right] \exp \left[-ie \int_{\xi_1}^{\xi_2} d\eta^\mu \partial_\mu \alpha(\eta) \right] = e^{ie[\alpha(\xi_1) - \alpha(\xi_2)]} \mathcal{U}_{(\xi_1, \xi_2)}, \quad (8)$$

which is exactly the transformation that we need to render Φ gauge invariant.

Since different processes require different paths along which the Wilson line must be evaluated [14, 18, 29, 30], we are now going to introduce the specific path that enters the definition of the transverse-momentum dependent correlator [14]. Consider a generic vector $v^\mu = (v^+, v^-, \mathbf{v}_\perp)$ in light-cone coordinates; for our purposes we can keep the plus component v^+ fixed at 0, since the fields in (2) are taken along the light-cone at $\xi^+ = 0$. We move in

¹ Here, and in the following, we take $e > 0$, meaning that the electron charge is equal to $-e$.

the v^- - \mathbf{v}_\perp plane and define Wilson lines along the v^- and \mathbf{v}_\perp directions as follows: in order to connect the points $(0, a^-, \mathbf{c}_\perp)$ and $(0, b^-, \mathbf{c}_\perp)$ along the minus direction, we introduce the longitudinal gauge link:

$$\mathcal{U}^{v^-}(a^-, b^-; \mathbf{c}_\perp) := \mathcal{P} \exp \left[-ie \int_{a^-}^{b^-} d\eta^- A^+(0, \eta^-, \mathbf{c}_\perp) \right], \quad (9)$$

while in order to connect the points $(0, c^-, \mathbf{a}_\perp)$ and $(0, c^-, \mathbf{b}_\perp)$, along the transverse direction, we use the transverse gauge link:

$$\mathcal{U}^\perp(\mathbf{a}_\perp, \mathbf{b}_\perp; c^-) := \mathcal{P} \exp \left[ie \int_{\mathbf{a}_\perp}^{\mathbf{b}_\perp} d\boldsymbol{\eta}_\perp \cdot \mathbf{A}_\perp(0, c^-, \boldsymbol{\eta}_\perp) \right]. \quad (10)$$

In order to link the points $0 = (0^-, \mathbf{0}_\perp)$ and $\xi = (\xi^-, \boldsymbol{\xi}_\perp)$ appearing in our correlator, we follow a path along the v^- direction all the way to infinity, then get to $\boldsymbol{\xi}_\perp$ along the transverse direction and finally go back to ξ^- , as shown in Fig. 2. To this purpose, we define:

$$\mathcal{U}_{(0,\infty)} := \mathcal{U}^{v^-}(0^-, \infty^-; \mathbf{0}_\perp) \mathcal{U}^\perp(\mathbf{0}_\perp, \infty_\perp; \infty^-), \quad (11)$$

$$\mathcal{U}_{(\infty,\xi)} := \mathcal{U}^\perp(\infty_\perp, \boldsymbol{\xi}_\perp; \infty^-) \mathcal{U}^{v^-}(\infty^-, \xi^-; \boldsymbol{\xi}_\perp). \quad (12)$$

We therefore define the gauge-invariant transverse-momentum dependent correlator as:

$$\Phi(x, \mathbf{k}_\perp; P, S) := \int \frac{d\xi^- d^2 \boldsymbol{\xi}_\perp}{(2\pi)^3} e^{ik \cdot \xi} \langle P, S | \bar{\psi}(0) \mathcal{U}_{(0,\infty)} \mathcal{U}_{(\infty,\xi)} \psi(\xi) | P, S \rangle \Big|_{\xi^+ = 0}. \quad (13)$$

It is clear that if we choose the light-cone gauge $A^+ = 0$, the longitudinal gauge link \mathcal{U}^{v^-} reduces to the identity; in this gauge, only the transverse gauge link survives, and this is crucial to maintain the gauge independence under residual gauge transformations, which can be fixed by imposing appropriate boundary conditions [13]. In Feynman gauge, instead, the longitudinal gauge link is non-trivial; however, the transverse gauge link does not give any contribution, because the boundary condition for the transverse component of the photon field is $\mathbf{A}_\perp(\infty) = 0$. In the following, we will discuss the differences between the two choices of the gauge in more detail.

The insertion of a gauge link brings about some changes to the correlator from a diagrammatic point of view [12, 14]. Wilson lines physically correspond to final and initial state interactions, i.e. they account for the (infinitely many, in principle) photons that can be absorbed or emitted by the incoming or outgoing particles. Some examples of this kind of interactions are shown in Fig. 3, where we gather all the α -order contributions to the correlator (diagrams (a) to (f)), along with a case of a higher-order contribution (diagram (g)). Diagrams (a) and (b) are actually of zeroth order in the gauge link, as they refer respectively to the handbag diagram we already discussed and to the correction due to the self-energy of the bare electron; diagrams (c) and (d) contain one gauge photon and they are hence described using the first order approximation of the Wilson line in the coupling constant e , while (e) and (f) are of second order in the expansion of the gauge link. We also notice that, in diagram (d), the photon loop is responsible for the virtual vertex correction, which contributes only at the endpoint $x = 1$, $\mathbf{k}_\perp = \mathbf{0}_\perp$; this is true also for the self-energy in diagram (b). Diagrams (e) and (f) are instead proportional to n_-^2 (with $n_-^\mu = (0, 1, \mathbf{0}_\perp)$) and can be neglected, unless the direction of the gauge link is *not* taken along the light-cone.

We remark here that a proper definition of TMDs must deal also with the endpoints and the occurrence of infrared and rapidity divergences, which can be regularized, e.g., by taking n_- to be off the light cone. These are critical issues

FIG. 2: Wilson lines connecting two points at $0 = (0^-, \mathbf{0}_\perp)$ and $\xi = (\xi^-, \boldsymbol{\xi}_\perp)$.

FIG. 3: Contributions to the correlator at different orders in α and in the gauge link. Notice that also the Hermitean conjugates of all diagrams should be taken into account.

in proving factorization theorems and introducing well-defined TMDs, both for QCD and QED. Careful investigations of these issues can be found in several papers and books (see, e.g., [15, 31–37]).

The correlator $\Phi(k; P, S)$ in (1) can be written as a combination of elements of a basis in Dirac space $\mathcal{D} := \{\mathbb{1}, \gamma^\mu, \gamma^5, \gamma^5 \gamma^\mu, i\sigma^{\mu\nu}\}$. Let us consider from now on the case of the transverse-momentum dependent correlator $\Phi(x, \mathbf{k}_\perp; P, S)$ defined in (2) [28, 38, 39]. We can choose a reference frame where the incoming dressed electron has no transverse momentum, i.e. $P = (P^+, P^-, \mathbf{0}_\perp)$, with $P^- = m^2/2P^+$ for the on-shell condition. Moreover, since it must be $P \cdot S = 0$, $S^2 = -1$, we can set $S \equiv (S_z P^+/m, -S_z m/2P^+, \mathbf{S}_\perp)$ and therefore replace the dependence on the covariant four-vector S by the dependence on the three-vector $\mathbf{S} := (\mathbf{S}_\perp, S_z)$, with $\mathbf{S}^2 = 1$.

Introducing also the light-like vector $n_+ = (1, 0, \mathbf{0}_\perp)$ and the antisymmetric tensor:

$$\epsilon_{\perp}^{12} = -\epsilon_{\perp}^{21} = 1, \quad \epsilon_{\perp}^{11} = \epsilon_{\perp}^{22} = 0, \quad (14)$$

one finds, in the leading twist approximation:

$$\begin{aligned} \Phi \approx \frac{1}{2} \left[f_1^e \not{n}_+ - \frac{\epsilon_{\perp}^{ij} k_{\perp}^i S_{\perp}^j}{m} f_{1T}^{\perp e} \not{n}_+ + S_z g_{1L}^e \gamma^5 \not{n}_+ + \frac{\mathbf{k}_\perp \cdot \mathbf{S}_\perp}{m} g_{1T}^e \gamma^5 \not{n}_+ + \frac{[\not{k}_\perp, \not{n}_+]}{2} \gamma^5 h_{1T}^{\perp e} \right. \\ \left. + S_z \frac{[\not{k}_\perp, \not{n}_+]}{2m} \gamma^5 h_{1L}^{\perp e} + \frac{\mathbf{k}_\perp \cdot \mathbf{S}_\perp [\not{k}_\perp, \not{n}_+]}{2m^2} \gamma^5 h_{1T}^{\perp e} + \frac{i[\not{k}_\perp, \not{n}_+]}{2m} h_1^{\perp e} \right], \end{aligned} \quad (15)$$

where $i, j = 1, 2$ and $a_\perp^\mu = (0, 0, \mathbf{a}_\perp)$. In the above equation we introduced the leading twist transverse-momentum dependent (TMDs) distribution functions of an electron inside the dressed electron, f_1^e , $f_{1T}^{\perp e}$, g_{1L}^e , g_{1T}^e , h_{1T}^e , $h_{1L}^{\perp e}$, $h_1^{\perp e}$, that depend on (x, \mathbf{k}_\perp^2) . As far as the notation is concerned, the letters f , g and h refer to an unpolarized, longitudinally polarized and transversely polarized internal electron; L (T) refers to the spin of the dressed electron being along the longitudinal (transverse) direction; the “ \perp ” symbols signals an explicit dependence on transverse momenta with an uncontracted index. Out of the eight TMDs in Eq. (15), the so-called Boer-Mulders function $h_1^{\perp e}$ [40] and the Sivers function $f_{1T}^{\perp e}$ [41] are T-odd, i.e. they change sign under naive time reversal, which is defined as usual time-reversal but without interchange of initial and final states, while the other six are T-even.

Let us take the trace of the correlator multiplied by an appropriate Dirac operator and define:

$$\Phi^{[\Gamma]}(x, \mathbf{k}_\perp; \mathbf{S}) := \frac{1}{2} \text{Tr} [\Phi(x, \mathbf{k}_\perp; \mathbf{S}) \Gamma], \quad (16)$$

with $\Gamma \in \mathcal{D}$. It turns out that, at the leading twist in $1/Q$, these Dirac space projections are given by [28, 39]:

$$\Phi^{[\gamma^+]}(x, \mathbf{k}_\perp; \mathbf{S}) = f_1^e - \frac{\epsilon_{\perp}^{ij} k_{\perp}^i S_{\perp}^j}{m} f_{1T}^{\perp e}, \quad (17)$$

$$\Phi^{[\gamma^+ \gamma^5]}(x, \mathbf{k}_\perp; \mathbf{S}) = S_z g_{1L}^e + \frac{\mathbf{k}_\perp \cdot \mathbf{S}_\perp}{m} g_{1T}^e, \quad (18)$$

$$\Phi^{[i\sigma^{j+} \gamma^5]}(x, \mathbf{k}_\perp; \mathbf{S}) = S_{\perp}^j h_1^e + S_z \frac{k_{\perp}^j}{m} h_{1L}^{\perp e} + S_{\perp}^i \frac{2k_{\perp}^i k_{\perp}^j - \mathbf{k}_\perp^2 \delta^{ij}}{2m^2} h_{1T}^{\perp e} + \frac{\epsilon_{\perp}^{ji} k_{\perp}^i}{m} h_1^{\perp e}, \quad (19)$$

FIG. 4: Diagrams contributing to the TMDs in Feynman gauge, for $x \neq 1$ and $\mathbf{k}_\perp \neq \mathbf{0}_\perp$.

where

$$h_1^e := h_{1T}^e + \frac{\mathbf{k}_\perp^2}{2m^2} h_{1T}^{\perp e}. \quad (20)$$

The different TMDs in Eq. (17)-(19) can be isolated by taking proper spin configurations of the dressed electron, while the Dirac structure Γ in the field correlator projects on different polarization states of the internal bare electron.

III. CALCULATION OF TMDs IN FEYNMAN GAUGE

In this section, we derive explicit analytic expressions for the TMDs. We stress that, from now on, we will exclude the end-point $x = 1, \mathbf{k}_\perp = \mathbf{0}_\perp$ from our analysis, since it would require a proper regularization procedure which is beyond the scope of the present work. This implies that we will neglect in our analysis all self-energy and virtual vertex corrections discussed in section II (diagrams (b) and (d) in Fig. 3).

An important statement can be done straightforwardly about the T-odd TMDs $f_{1T}^{\perp e}$ and $h_{1T}^{\perp e}$. Had we tried to derive them starting from the correlator without the gauge link, i.e. the one in Eq. (2), we would have found that they are vanishing. This, eventually, can be explained by the fact that only diagrams containing a loop at one side of the cut (such as diagrams (d) to (g) in Fig. 3) can potentially give a non-zero contributions to T-odd TMDs [14]. The only possibility to have such a loop is either to consider diagrams of higher perturbative order, or consider the end-point $x = 1, \mathbf{k}_\perp = \mathbf{0}_\perp$. Therefore, already at this stage we are allowed to conclude that *at order α and for $x \neq 1, \mathbf{k}_\perp \neq \mathbf{0}_\perp$, we have:*

$$h_{1T}^{\perp e}(x, \mathbf{k}_\perp^2) = 0, \quad (21)$$

$$f_{1T}^{\perp e}(x, \mathbf{k}_\perp^2) = 0. \quad (22)$$

As we mentioned, from a diagrammatic point of view, the correlator (1) corresponds to the diagram shown in the right-hand side of Fig. 1; it is possible, then, to evaluate it with usual Feynman rules and take its trace with a proper matrix Γ , in order to recover the analytic expressions of the TMDs. Introducing for greater clarity the Dirac indices, the scattering amplitude reads:

$$|\mathcal{M}|^2 = \frac{1}{(2\pi)^3} \delta((P-k)^2) \delta((k+q)^2 - m^2) \bar{u}_{S,i}(\mathbf{P}) M_{ij}^{\text{low}} M_{jk}^{\text{up}} u_{S,k}(\mathbf{P}), \quad (23)$$

where we factored out the transition matrix corresponding to the lower part of the diagram:

$$\mathcal{M}_{ij}^{\text{low}} = e^2 d^{\mu\nu}(P-k) \left(\gamma_\nu \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \right)_{il} \left(\frac{\not{k} + m}{k^2 - m^2 + i\epsilon} \gamma_\mu \right)_{lj} \quad (24)$$

from the one corresponding to the upper part, where the interaction between the parton electron and the virtual photon takes place:

$$\mathcal{M}_{jk}^{\text{up}} = e^2 \left(\not{\epsilon}_\lambda^*(\mathbf{q})(\not{k} + \not{q} + m) \not{\epsilon}_\lambda(\mathbf{q}) \right)_{jk}.$$

We can henceforth write for the correlator, setting the Dirac indices according to (1):

$$\Phi(k; \mathbf{S})_{ij} = \frac{e^2}{(2\pi)^3} \delta((P-k)^2) \bar{u}_{S,k}(\mathbf{P}) d^{\mu\nu}(P-k) \left(\gamma_\nu \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \right)_{kj} \left(\frac{\not{k} + m}{k^2 - m^2 + i\epsilon} \gamma_\mu \right)_{il} u_{S,l}(\mathbf{P}). \quad (25)$$

FIG. 5: Handbag diagram with a photon loop separated into its upper and lower part, with the latter corresponding to the correlator. The two factorized subdiagrams are meant to be “attached” by joining the crosses with the crosses and the circles with circles.

The sum over photon polarization vectors $d_{\mu\nu}$ takes different forms depending on the gauge. We choose the Feynman gauge first, and hence use:

$$d^{\mu\nu}(p) := \sum_{\lambda} \varepsilon_{\lambda}^{\mu *}(\mathbf{p}) \varepsilon_{\lambda}^{\nu}(\mathbf{p}) = -g^{\mu\nu}. \quad (26)$$

As far as the denominator of (24) is concerned, we have:

$$\begin{aligned} \frac{1}{k^2 - m^2 - i\epsilon} \frac{1}{k^2 - m^2 + i\epsilon} &= \left[\text{P.V.} \left(\frac{1}{k^2 - m^2} \right) + i\pi\delta(k^2 - m^2) \right] \left[\text{P.V.} \left(\frac{1}{k^2 - m^2} \right) - i\pi\delta(k^2 - m^2) \right] \\ &= \text{P.V.} \left(\frac{1}{(k^2 - m^2)^2} \right) + \pi^2\delta(k^2 - m^2), \end{aligned} \quad (27)$$

where P.V. stands for principal value distribution. The delta function in the above equation can be dropped, because it is not compatible with the overall momentum conservation. We are allowed to keep the denominator $1/(k^2 - m^2)^2$, in the sense of a principal value distribution.

As an example, we would like to show the result for the TMD $f_1^e(x, \mathbf{k}_{\perp}^2)$, which is the distribution for unpolarized electrons in an unpolarized dressed electron. From Eq. (17), since it is $f_{1T}^{\perp e} = 0$, we see that f_1^e can be recovered by taking the trace of $\Phi\gamma^+$ (with a factor 1/2) and including also an average over the spin state of the target electron. We rewrite also:

$$\delta((P - k)^2) = \frac{1}{2(P - k)^+} \delta\left(k^- - P^- + \frac{\mathbf{k}_{\perp}^2}{2(P - k)^+}\right),$$

where, from the on-shell condition, $P^- = m^2/(2P^+)$ (working in a frame of reference where $\mathbf{P}_{\perp} = \mathbf{0}_{\perp}$). Hence, it is easy to find that the contribution of diagram (a) of Fig. 4 to the TMD f_1^e is

$$\begin{aligned} f_1^a(x, \mathbf{k}_{\perp}^2) &= \sum_S \int dk^- \frac{1}{8(2\pi)^3(P - k)^+} \delta\left(k^- - P^- + \frac{\mathbf{k}_{\perp}^2}{2(P - k)^+}\right) \frac{(-e^2)}{(k^2 - m^2)^2} [\bar{u}_S(\mathbf{P})\gamma_{\mu}(\not{k} + m)\gamma^+(\not{k} + m)\gamma^{\mu}u_S(\mathbf{P})] \\ &= \frac{1}{(2\pi)^3} \left[\frac{\mathbf{k}_{\perp}^2 + m^2(1 - 4x + x^2)}{x} \right] \varphi^2(x, \mathbf{k}_{\perp}^2), \end{aligned} \quad (28)$$

where the function $\varphi(x, \mathbf{k}_{\perp}^2)$ is defined as:

$$\varphi(x, \mathbf{k}_{\perp}^2) := \frac{e\sqrt{x(1-x)}}{[(1-x)^2m^2 + \mathbf{k}_{\perp}^2]}. \quad (29)$$

This is not actually the final result, since we have not yet considered the longitudinal gauge link, which is not vanishing in the Feynman gauge and brings about two more diagrams to be evaluated, namely diagram (b) and (c) of Fig. 4. The scattering amplitude for diagram (b) reads:²

$$|\mathcal{M}|^2 = -e^4 \bar{u}_S(\mathbf{P})\gamma_{\nu}g^{\mu\nu} \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \not{\epsilon}_{\lambda}^*(\mathbf{q})(\not{k} + \not{q} + m)\gamma_{\mu} \frac{\not{k} + \not{q} + \not{l} + m}{(k + q + l)^2 - m^2 + i\epsilon} \not{\epsilon}_{\lambda}(\mathbf{q})u_S(\mathbf{P}). \quad (30)$$

² It is convenient to set the momentum of the dressed electron as $P = k + l$.

In order to separate the term corresponding to the lower part, this time we need to apply the so-called *eikonal approximation* [31, 42], which consists into considering as relevant only the “−” component of the momentum of the fermion after the interaction with the virtual photon; moreover, it is assumed that the emission or the absorption of a “soft” photon, with small momentum l , does not alter the fermion momentum. It can be shown that, under this approximation, the propagator of the struck fermion becomes:

$$\frac{\not{k} + \not{q} + \not{l} + m}{(k + q + l)^2 - m^2 + i\epsilon} \simeq \frac{\gamma^+}{2l^+ + i\epsilon} . \quad (31)$$

In this way we are able to factor out a lower and an upper part in the amplitude, since:

$$(\not{k} + \not{q} + m)\gamma^\rho\gamma^+ \simeq (k + q)^-\gamma^+\gamma^\rho\gamma^+ = 2(k + q)^-\gamma^+ \simeq 2(\not{k} + \not{q} + m) , \quad (32)$$

where in the first and in the last step we applied again the eikonal approximation and in the second step we assumed $\rho \equiv -$ to obtain a non-zero result. The modified propagator described in Eq. (31) is shown in the right-hand side of Fig. 5; the eikonal approximation is taken into account by using the modified Feynman rules for the eikonal propagator and vertex described in Fig. 6.

$$\text{Diagram 1} = \frac{i}{l^+ + i\epsilon}, \quad \text{Diagram 2} = -ie n_-^\mu . \quad (33)$$

FIG. 6: Feynman rules for the eikonal propagator (left) and vertex (right), when appearing on the left-hand side of cut diagrams. Notice that the momentum in the propagator is equal to the momentum of the photon attached to vertex.

The resulting transition matrix for the lower part of the diagram in Fig. 5 is now:

$$\mathcal{M}_{ij}^{\text{low}} = -\frac{e^2}{l^+ + i\epsilon} g^{\mu\nu} \left(\gamma_\nu \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \right)_{ij} n_{-\mu} . \quad (34)$$

Let us focus the attention on the denominators first. We have:

$$\begin{aligned} \frac{1}{l^+ + i\epsilon} \frac{1}{k^2 - m^2 - i\epsilon} &= \left[\text{P.V.} \left(\frac{1}{l^+} \right) - i\pi\delta(l^+) \right] \left[\text{P.V.} \left(\frac{1}{k^2 - m^2} \right) + i\pi\delta(k^2 - m^2) \right] \\ &= \frac{1}{l^+(k^2 - m^2)} + i\pi \left[\text{P.V.} \left(\frac{1}{l^+} \right) \delta(k^2 - m^2) - \text{P.V.} \left(\frac{1}{k^2 - m^2} \right) \delta(l^+) \right] + \pi^2 \delta(l^+) \delta(k^2 - m^2) . \end{aligned} \quad (35)$$

The $\delta(k^2 - m^2)$, as we already noticed, is not compatible with overall conservation of momentum, and therefore must be dropped; the term with $\delta(l^+)$ instead will be canceled by the contribution of diagram (c) of Fig. 4, as the imaginary unit from the photon vertex changes sign, being on the right-hand side of the cut. Therefore once again we are allowed to drop all the $i\epsilon$ in the denominators. If we derive the correlator corresponding to the amplitude (34), as we did in (25) starting from (24), we obtain that the contribution of diagram (b) to the TMD f_1^e is

$$f_1^b(x, \mathbf{k}_\perp^2) = \frac{1}{(2\pi)^3} \left[\frac{\mathbf{k}_\perp^2 + m^2(1-x)^2}{(1-x)^2} \right] \varphi^2(x, \mathbf{k}_\perp^2) . \quad (36)$$

A completely equivalent result is found by computing the contribution f_1^c to f_1^e from diagram (c); henceforth we have $f_1^c = f_1^b$ and we can finally write as a final result

$$f_1^e(x, \mathbf{k}_\perp^2) = f_1^a(x, \mathbf{k}_\perp^2) + f_1^b(x, \mathbf{k}_\perp^2) + f_1^c(x, \mathbf{k}_\perp^2) = \frac{1}{(2\pi)^3} \left[\frac{(1+x^2)\mathbf{k}_\perp^2 + m^2(1-x)^4}{x(1-x)^2} \right] \varphi^2(x, \mathbf{k}_\perp^2) . \quad (37)$$

The same procedure can be applied to all the TMDs; as a result, we find that the leading-twist TMDs, at $(x, \mathbf{k}_\perp) \neq$

$(1, \mathbf{0})$ are:

$$f_1^e(x, \mathbf{k}_\perp) = \frac{1}{(2\pi)^3} \left[\frac{\mathbf{k}_\perp^2(1+x^2) + m^2(1-x)^4}{x(1-x)^2} \right] \varphi^2(x, \mathbf{k}_\perp^2) = \frac{e^2}{(2\pi)^3} \frac{\mathbf{k}_\perp^2(1+x^2) + m^2(1-x)^4}{(1-x)[\mathbf{k}_\perp^2 + m^2(1-x)^2]^2}, \quad (38)$$

$$g_{1L}^e(x, \mathbf{k}_\perp) = \frac{1}{(2\pi)^3} \left[\frac{\mathbf{k}_\perp^2(1+x^2) - m^2(1-x)^4}{x(1-x)^2} \right] \varphi^2(x, \mathbf{k}_\perp^2) = \frac{e^2}{(2\pi)^3} \frac{\mathbf{k}_\perp^2(1+x^2) - m^2(1-x)^4}{(1-x)[\mathbf{k}_\perp^2 + m^2(1-x)^2]^2}, \quad (39)$$

$$g_{1T}^e(x, \mathbf{k}_\perp^2) = -\frac{2m^2}{(2\pi)^3} \varphi^2(x, \mathbf{k}_\perp^2) = -\frac{2e^2}{(2\pi)^3} m^2 \frac{x(1-x)}{[\mathbf{k}_\perp^2 + m^2(1-x)^2]^2}, \quad (40)$$

$$h_{1L}^{\perp e}(x, \mathbf{k}_\perp^2) = \frac{2m^2}{(2\pi)^3 x} \varphi^2(x, \mathbf{k}_\perp^2) = \frac{2e^2}{(2\pi)^3} m^2 \frac{(1-x)}{[\mathbf{k}_\perp^2 + m^2(1-x)^2]^2}, \quad (41)$$

$$h_{1T}^{\perp e}(x, \mathbf{k}_\perp^2) = 0, \quad (42)$$

$$h_1^e(x, \mathbf{k}_\perp^2) = \frac{2}{(2\pi)^3} \frac{\mathbf{k}_\perp^2}{(1-x)^2} \varphi^2(x, \mathbf{k}_\perp^2) = \frac{2e^2}{(2\pi)^3} \frac{x\mathbf{k}_\perp^2}{(1-x)[\mathbf{k}_\perp^2 + m^2(1-x)^2]^2}, \quad (43)$$

$$h_1^{\perp e}(x, \mathbf{k}_\perp^2) = f_{1T}^{\perp e}(x, \mathbf{k}_\perp^2) = 0. \quad (44)$$

IV. CALCULATION OF TMDs IN LIGHT-CONE GAUGE

A. Overlap representation

We now switch to the light-cone gauge, aiming to recover the same results that we found in the Feynman gauge. We will also apply a different approach, adopting the formalism of light-cone quantization and thus obtaining an overlap representation of TMDs in terms of LFWFs [9, 43, 44].

We already remarked that the longitudinal gauge link is simply an identity in the light-cone gauge; we also neglect, at least at this level, the contribution coming from the transverse gauge link, that we will study separately later. Therefore, the expression we should start with is (2). Taking the trace of a generic Dirac operator Γ is equivalent to rewriting [28]:

$$\Phi^{[\Gamma]}(x, \mathbf{k}_\perp; \mathbf{S}) = \int \frac{d\xi^- d^2\xi_\perp}{2(2\pi)^3} e^{-ik\xi} \langle P, \mathbf{S} | \bar{\psi}(\xi) \Gamma \psi(0) | P, \mathbf{S} \rangle \Big|_{\xi^+=0}. \quad (45)$$

We expand the eigenstate $|P, \mathbf{S}\rangle$ of the electron in the light-cone Fock space [43] truncating the expansion to the two-particle Fock state of a photon and an electron. Since we are going to use light-cone quantization, we need to decompose the dressed electron states in terms of light-cone helicity states $|P, \Lambda\rangle$, where in the following $\Lambda = \pm$ stands for the values of light-front helicity $\pm 1/2$. If we have $\mathbf{S} = (\sin\theta \cos\phi, \sin\theta \sin\phi, \cos\theta)$, then we need to transform the basis $(|P, \mathbf{S}\rangle, |P, -\mathbf{S}\rangle)$ according to [45]:

$$\begin{pmatrix} |P, \mathbf{S}\rangle \\ |P, -\mathbf{S}\rangle \end{pmatrix} = \begin{pmatrix} \cos \frac{\theta}{2} e^{-i\phi/2} & \sin \frac{\theta}{2} e^{i\phi/2} \\ \cos \frac{\theta}{2} e^{-i\phi/2} & -\sin \frac{\theta}{2} e^{-i\phi/2} \end{pmatrix} \begin{pmatrix} |P, +\rangle \\ |P, -\rangle \end{pmatrix}. \quad (46)$$

In this representation, we then have:

$$|P, \Lambda\rangle = Z|e\rangle + |e\gamma\rangle. \quad (47)$$

In the above equation Z is a renormalization constant that we may simply take to be 1 for our purposes (it would become relevant only when considering the end-point $x = 1, \mathbf{k}_\perp = \mathbf{0}_\perp$). The one-particle state is simply:

$$|e\rangle = b_\Lambda^\dagger(\mathbf{P})|0\rangle, \quad (48)$$

with $b_\Lambda^\dagger(\mathbf{P})$ the creation operator of an electron with light-cone helicity Λ and momentum $\mathbf{P} = (P^+, \mathbf{P}_\perp)$.

In order to find the exact expression of the multi-particle Fock states, one should solve the eigenvalue equation for the full QED Hamiltonian. However, by considering the interaction potential small with respect to the free

Hamiltonian, one is allowed to apply time-ordered perturbation theory and, for the two-particle state at first order in the coupling constant e , one finds [44]:

$$|e\gamma\rangle = \int \frac{dx d^2\mathbf{k}_\perp}{2(2\pi)^3 \sqrt{x(1-x)}} \sum_{\lambda, \lambda_\gamma} \Psi_{\lambda, \lambda_\gamma}^\Lambda(x, \mathbf{k}_\perp) |e\gamma; \mathbf{p}_e, \lambda; \mathbf{p}_\gamma, \lambda_\gamma\rangle. \quad (49)$$

Here $\lambda = \pm$, $\lambda_\gamma = \pm 1$ stand for the internal electron helicity $\pm 1/2$ and photon polarization, respectively, and $\mathbf{p}_e, \mathbf{p}_\gamma$ refer to the momenta of the partons:³

$$\mathbf{p}_e = (xP^+, \mathbf{k}_\perp), \quad \mathbf{p}_\gamma = ((1-x)P^+, -\mathbf{k}_\perp). \quad (50)$$

The wave functions $\Psi_{\lambda, \lambda_\gamma}^\Lambda(x, \mathbf{k}_\perp)$ appearing in (49) are given by:

$$\Psi_{\lambda, \lambda_\gamma}^\Lambda(x, \mathbf{k}_\perp) = \varphi(x, \mathbf{k}_\perp^2) \bar{u}_\lambda(\mathbf{p}_e) \gamma^\mu \varepsilon_{\lambda_\gamma, \mu}^*(\mathbf{p}_\gamma) u_\Lambda(\mathbf{P}), \quad (51)$$

with the function $\varphi(x, \mathbf{k}_\perp^2)$ defined in Eq. (29). In the light-cone gauge $A^+ = 0$, they are the LFWFs for the $|e\gamma\rangle$ component of the dressed electron. For a dressed electron with LF helicity $\Lambda = +$, one has explicitly⁴ [9]:

$$\Psi_{+, +1}^+(x, \mathbf{k}_\perp) = \sqrt{\frac{2}{x}} \frac{(k_x - ik_y)}{(1-x)} \varphi(x, \mathbf{k}_\perp^2), \quad (52)$$

$$\Psi_{+, -1}^+(x, \mathbf{k}_\perp) = -\sqrt{2x} \frac{(k_x + ik_y)}{(1-x)} \varphi(x, \mathbf{k}_\perp^2), \quad (53)$$

$$\Psi_{-, +1}^+(x, \mathbf{k}_\perp) = \sqrt{\frac{2}{x}} m(1-x) \varphi(x, \mathbf{k}_\perp^2), \quad (54)$$

$$\Psi_{-, -1}^+(x, \mathbf{k}_\perp) = 0. \quad (55)$$

Assuming instead $\Lambda = -$ one has:

$$\Psi_{+, +1}^-(x, \mathbf{k}_\perp) = 0, \quad (56)$$

$$\Psi_{+, -1}^-(x, \mathbf{k}_\perp) = \sqrt{\frac{2}{x}} m(1-x) \varphi(x, \mathbf{k}_\perp^2), \quad (57)$$

$$\Psi_{-, +1}^-(x, \mathbf{k}_\perp) = \sqrt{2x} \frac{(k_x - ik_y)}{(1-x)} \varphi(x, \mathbf{k}_\perp^2), \quad (58)$$

$$\Psi_{-, -1}^-(x, \mathbf{k}_\perp) = -\sqrt{\frac{2}{x}} \frac{(k_x + ik_y)}{(1-x)} \varphi(x, \mathbf{k}_\perp^2). \quad (59)$$

Notice that the LFWFs in Eqs. (52)-(59) are related by

$$\Psi_{\lambda, \lambda_\gamma}^\Lambda(x, \mathbf{k}_\perp) = (-1)^{(\Lambda-\lambda)/2+\lambda_\gamma} \Psi_{-\lambda, -\lambda_\gamma}^{-\Lambda*}(x, \mathbf{k}_\perp). \quad (60)$$

If we use Eq. (47) in the correlator (45), and take the proper projections for each Γ matrix, we can obtain the LFWF overlap representation of the correlator, which reads:

$$\Phi^{[\Gamma]}(x, \mathbf{k}_\perp; \Lambda) = \frac{1}{4(2\pi)^3 x P^+} \sum_{\lambda, \lambda', \lambda_\gamma} \Psi_{\lambda', \lambda_\gamma}^{\Lambda*}(x, \mathbf{k}_\perp) \bar{u}_{\lambda'}(\mathbf{p}_e) \Gamma u_\Lambda(\mathbf{p}_e) \Psi_{\lambda, \lambda_\gamma}^\Lambda(x, \mathbf{k}_\perp). \quad (61)$$

An alternative, yet equivalent, way to derive the TMDs explicitly is to represent the correlator in the basis where we consider the helicity of both the dressed and the internal electron and we treat them symmetrically. We can therefore define the helicity amplitudes [45]:

$$\Phi_{\Lambda', \lambda'; \Lambda, \lambda}(x, \mathbf{k}_\perp) := \frac{1}{N} \langle P, \Lambda' | b_{\lambda'}^\dagger(x, \mathbf{k}_\perp) b_\lambda(x, \mathbf{k}_\perp) | P, \Lambda \rangle, \quad (62)$$

³ One should pay attention not confusing the $|e\gamma\rangle$ state, which describes the dressed electron as a 2-body system in Eq. (47), with the state of two free quanta $|e\gamma; \mathbf{p}_e, \lambda; \mathbf{p}_\gamma, \lambda_\gamma\rangle$.

⁴ There is a sign difference with respect to Ref. [9], due to a different choice of the sign of the charge e .

with

$$N := [2(2\pi)^3]^2 x \delta^{(3)}(\mathbf{0}) .$$

Inserting in (62) the Fock-state expansion (47), we obtain

$$\Phi_{\Lambda', \lambda'; \Lambda, \lambda}(x, \mathbf{k}_\perp) = \frac{1}{2(2\pi)^3} \sum_{\lambda_\gamma} \Psi_{\lambda', \lambda_\gamma}^{\Lambda' *} (x, \mathbf{k}_\perp) \Psi_{\lambda, \lambda_\gamma}^\Lambda (x, \mathbf{k}_\perp) . \quad (63)$$

The helicity amplitudes are parametrized by the following combinations of TMDs [45, 46]:

$$\Phi = \begin{pmatrix} \frac{1}{2}(f_1^e + g_{1L}^e) & -\frac{k_R}{2m}(ih_1^{\perp e} - h_{1L}^{\perp e}) & \frac{k_L}{2m}(if_{1T}^{\perp e} + g_{1T}^e) & h_1^e \\ \frac{k_L}{2m}(ih_1^{\perp e} + h_{1L}^{\perp e}) & \frac{1}{2}(f_1^e - g_{1L}^e) & \frac{k_L^2}{2m^2}h_{1T}^{\perp e} & \frac{k_L}{2m}(if_{1T}^{\perp e} - g_{1T}^e) \\ -\frac{k_R}{2m}(if_{1T}^{\perp e} - g_{1T}^e) & \frac{k_R^2}{2m^2}h_{1T}^{\perp e} & \frac{1}{2}(f_1^e - g_{1L}^e) & -\frac{k_R}{2m}(ih_1^{\perp e} + h_{1L}^{\perp e}) \\ h_1^e & -\frac{k_R}{2m}(if_{1T}^{\perp e} + g_{1T}^e) & \frac{k_L}{2m}(ih_1^{\perp e} - h_{1L}^{\perp e}) & \frac{1}{2}(f_1^e + g_{1L}^e) \end{pmatrix} \quad (64)$$

where $k_{R,L} := k_x \pm ik_y$. The row entries are $(\Lambda', \lambda') = (++) , (+-) , (-+) , (--)$, while the column entries are $(\Lambda, \lambda) = (++) , (+-) , (-+) , (--)$.

Using Eq. (61) and the projections (17)-(19), or equivalently Eq. (63) along with (64), one obtains the following results for the LFWF overlap representation of the contribution of the internal electron to the T-even TMDs:

$$f_1^e(x, \mathbf{k}_\perp^2) = \frac{1}{4(2\pi)^3} \sum_{\Lambda, \lambda, \lambda_\gamma} |\Psi_{\lambda, \lambda_\gamma}^\Lambda(x, \mathbf{k}_\perp)|^2 = \frac{1}{2(2\pi)^3} [|\Psi_{+,+1}^+(x, \mathbf{k}_\perp)|^2 + |\Psi_{+,-1}^+(x, \mathbf{k}_\perp)|^2 + |\Psi_{-,+1}^+(x, \mathbf{k}_\perp)|^2] , \quad (65)$$

$$g_{1L}^e(x, \mathbf{k}_\perp^2) = \frac{1}{2(2\pi)^3} [|\Psi_{+,+1}^+(x, \mathbf{k}_\perp)|^2 + |\Psi_{+,-1}^+(x, \mathbf{k}_\perp)|^2 - |\Psi_{-,+1}^+(x, \mathbf{k}_\perp)|^2] , \quad (66)$$

$$g_{1T}^e(x, \mathbf{k}_\perp^2) = \frac{m}{4(2\pi)^3 \mathbf{k}_\perp^2} \sum_{\lambda_\gamma} \left[k_R \Psi_{+, \lambda_\gamma}^{+*}(x, \mathbf{k}_\perp) \Psi_{+, \lambda_\gamma}^-(x, \mathbf{k}_\perp) + k_L \Psi_{+, \lambda_\gamma}^{-*}(x, \mathbf{k}_\perp) \Psi_{+, \lambda_\gamma}^+(x, \mathbf{k}_\perp) \right] , \quad (67)$$

$$h_{1L}^{\perp e}(x, \mathbf{k}_\perp^2) = \frac{m}{2(2\pi)^3 \mathbf{k}_\perp^2} \sum_{\lambda_\gamma} \left[k_R \Psi_{-, \lambda_\gamma}^{+*}(x, \mathbf{k}_\perp) \Psi_{+, \lambda_\gamma}^+(x, \mathbf{k}_\perp) + k_L \Psi_{+, \lambda_\gamma}^{+*}(x, \mathbf{k}_\perp) \Psi_{-, \lambda_\gamma}^+(x, \mathbf{k}_\perp) \right] , \quad (68)$$

$$h_{1T}^{\perp e}(x, \mathbf{k}_\perp^2) = \frac{m^2}{2(2\pi)^3 \mathbf{k}_\perp^2} \sum_{\lambda_\gamma} \left[k_R^2 \Psi_{-, \lambda_\gamma}^{+*}(x, \mathbf{k}_\perp) \Psi_{+, \lambda_\gamma}^-(x, \mathbf{k}_\perp) + k_L^2 \Psi_{+, \lambda_\gamma}^{-*}(x, \mathbf{k}_\perp) \Psi_{-, \lambda_\gamma}^+(x, \mathbf{k}_\perp) \right] , \quad (69)$$

$$h_1^e(x, \mathbf{k}_\perp^2) = \frac{1}{2(2\pi)^3} \left[\Psi_{+,+1}^{+*}(x, \mathbf{k}_\perp) \Psi_{-,+1}^-(x, \mathbf{k}_\perp) + \Psi_{+,-1}^{+*}(x, \mathbf{k}_\perp) \Psi_{-,-1}^-(x, \mathbf{k}_\perp) \right] . \quad (70)$$

The analytic results found by inserting the explicit expressions (52)-(59) of the LFWFs indeed coincide with the results (38)-(44) obtained in Feynman gauge and using Feynman diagrams.

The LFWFs are eigenstates of the total spin of the partons in the z direction, $J_z = \lambda/2 + \lambda_\gamma$, and of the total OAM $L_z = \Lambda/2 - J_z$, as required by angular momentum conservation. For the two-body LFWFs of the electron, one can have only $L_z = 0$, and $L_z = \pm 1$. They are commonly labeled as S and P waves, respectively, although this is an abuse of language as partial waves should refer to L and not L_z . The LFWF overlap representation in Eqs. (65)-(70) allows one to disclose the different contributions to the TMDs from the spin and OAM configurations of the partons. In particular, f_1^e , g_{1L}^e and h_1^e are all diagonal in the OAM, while the remaining TMDs contain different interference terms between S and P waves, and therefore involve a transfer of OAM between the initial and final electron state. The interplay between the different partial waves in the TMDs will be discussed in more detail in Sec. VII.

B. Feynman diagram approach

It is interesting to follow the diagrammatic approach in light-cone gauge also, in order to explicitly discuss the gauge invariance of TMDs. In this case, since the longitudinal gauge link is trivial, and we are neglecting for the moment the transverse gauge link, we only need to evaluate diagram (a) of Fig. 4; the amplitude is still given by (23), but this time we take the following sum over the photon polarization vectors:

$$d^{\mu\nu}(p) := \sum_\lambda \varepsilon_\lambda^{\mu*}(\mathbf{p}) \varepsilon_\lambda^\nu(\mathbf{p}) = -g^{\mu\nu} + \frac{1}{p^+} (p^\nu n_-^\mu - p^\mu n_-^\nu) . \quad (71)$$

If we factorize the amplitude separating the upper and lower part, we actually get three contributions for the lower part of the diagram:

$$\bar{u}_{\mathbf{S}}(\mathbf{P})\mathcal{M}^{\text{low}}u_{\mathbf{S}}(\mathbf{P}) \equiv A + B + C ,$$

with

$$A := -e^2 \bar{u}_{\mathbf{S}}(\mathbf{P}) \gamma_{\mu} \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \frac{\not{k} + m}{k^2 - m^2 + i\epsilon} \gamma^{\mu} u_{\mathbf{S}}(\mathbf{P}) , \quad (72)$$

$$B := \frac{e^2}{(P-k)^+} \bar{u}_{\mathbf{S}}(\mathbf{P}) \gamma^+ \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \frac{\not{k} + m}{k^2 - m^2 + i\epsilon} (\not{P} - \not{k}) u_{\mathbf{S}}(\mathbf{P}) . \quad (73)$$

$$C := \frac{e^2}{(P-k)^+} \bar{u}_{\mathbf{S}}(\mathbf{P}) (\not{P} - \not{k}) \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \frac{\not{k} + m}{k^2 - m^2 + i\epsilon} \gamma^+ u_{\mathbf{S}}(\mathbf{P}) , \quad (74)$$

It is now easy to recognize that the term A is equivalent to the contribution obtained from (24) evaluated in the Feynman gauge. Let us focus on B ; using the Dirac equation $(\not{P} - m)u_{\mathbf{S}}(\mathbf{P}) = 0$, we can rewrite:

$$\frac{\not{k} + m}{k^2 - m^2} (\not{P} - \not{k}) u_{\mathbf{S}}(\mathbf{P}) = \frac{\not{k} + m}{k^2 - m^2} (m - \not{k}) u_{\mathbf{S}}(\mathbf{P}) = -u_{\mathbf{S}}(\mathbf{P}) .$$

Hence we find that term B , which comes from the extra-term in the polarization sum in light-cone gauge, actually coincides with the contribution of Eq. (34), treated with the eikonal approximation. The same applies also to term C , which in turn corresponds to diagram (c) of Fig. 4 in Feynman gauge after eikonal approximation.

We can now also easily check that the term of the correlator that is related to diagram (b) and (c) of Fig. 4 are actually vanishing in the light-cone gauge. If we still use the eikonal approximation, but substitute the sum (71) instead of (26) for the polarization vectors in (34), the latter becomes:

$$\bar{u}_{\mathbf{S}}(\mathbf{P})\mathcal{M}^{\text{low}}u_{\mathbf{S}}(\mathbf{P}) = -\frac{e^2}{(p-k)^+ + i\epsilon} \bar{u}_{\mathbf{S}}(\mathbf{P}) \gamma_{\nu} \left[-g^{\mu\nu} + \frac{1}{p^+} (p^{\mu} n_{-}^{\nu} + p^{\nu} n_{-}^{\mu}) \right] \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} n_{-\mu} u_{\mathbf{S}}(\mathbf{P}) , \quad (75)$$

which contains the Dirac structure:

$$-\gamma^+ + \frac{1}{k^+} \gamma_{\mu} n_{-}^{\mu} k^{\nu} n_{-\nu} + \frac{1}{k^+} \not{k} n_{-}^2 = 0 .$$

Within the diagram approach in the light-cone gauge we recover the same results for the TMDs we obtained in the Feynman gauge derivation of section III.

V. TRANSVERSE GAUGE LINK

In the previous sections we performed the derivation of the TMDs for the electron first in Feynman gauge including the contribution from the longitudinal gauge link, then in light-cone gauge but neglecting the Wilson line; as a result, we found perfect agreement between the two gauges, as it should be since the TMDs are gauge-invariant objects. However, one may wonder if there is a contribution of the transverse gauge link. We actually neglected a correction to our results that is illustrative to analyze, although it will show up only at the end-point $x = 1$.

As it was noticed by Ji et al. [12, 13], the transverse gauge link does have an important role in taking into account the final state interactions when working in light-cone gauge. The point is that the four-momentum of the intermediate photon must be integrated over, according to cut-diagram rules. This means that, when we use the sum over the polarization vectors (71), we actually should regularize the singularity due to the p^+ factor in the denominator. We can in fact do this in different ways, because we have the freedom of choosing a certain prescription for the regularization of the denominator; the following choices are possible:

$$\text{Retarded : } \frac{1}{p^+} \longrightarrow \frac{1}{p^+ + i\epsilon} , \quad (76)$$

$$\text{Advanced : } \frac{1}{p^+} \longrightarrow \frac{1}{p^+ - i\epsilon} , \quad (77)$$

$$\text{Principal value : } \frac{1}{p^+} \longrightarrow \frac{1}{2} \left[\frac{1}{p^+ + i\epsilon} + \frac{1}{p^+ - i\epsilon} \right] . \quad (78)$$

It is obvious that our final result must be independent of the choice of a specific prescription, and it must also be the same we found in Feynman gauge, where the problem of regularizing the denominators does not arise and the transverse gauge link does not contribute. Nonetheless, if we come back to our evaluation of the TMD $f_1^e(x, \mathbf{k}_\perp^2)$ from Feynman diagrams, we see that it is not the case if we make the replacement (76)-(78) in (71) and then put the latter in the amplitude (24).

Let us first take the retarded prescription as an example: term A in (72) would be unchanged, but the denominator of terms B and C in (73) and (74) would be modified according to (76), giving:

$$B = \frac{e^2}{(P-k)^+ + i\epsilon} \bar{u}_S(\mathbf{P}) \gamma^+ \frac{\not{k} + m}{k^2 - m^2 - i\epsilon} \frac{\not{k} + m}{k^2 - m^2 + i\epsilon} (\not{P} - \not{k}) u_S(\mathbf{P}) , \quad (79)$$

and similarly for C . We rewrite, as usual:

$$\frac{1}{(P-k)^+ + i\epsilon} = \text{P.V.} \left(\frac{1}{(P-k)^+} \right) - i\pi \delta((P-k)^+) . \quad (80)$$

This leads us to the final result for the TMD f_1^e (including all three terms):

$$\begin{aligned} f_1^{\text{ret}}(x, \mathbf{k}_\perp^2) &= \frac{1}{(2\pi)^3} \left[\mathbf{k}_\perp^2 \frac{(1+x^2)}{x(1-x)^2} + m^2 \frac{(1-x)^2}{x} \right] \varphi^2(x, \mathbf{k}_\perp^2) - \frac{i}{(2\pi)^2} \left[\frac{\mathbf{k}_\perp^2}{1-x} + m^2(1-x) \right] \varphi^2(x, \mathbf{k}_\perp^2) \delta(1-x) \\ &= f_1^e(x, \mathbf{k}_\perp^2) - i \frac{e^2}{(2\pi)^2} \frac{1}{\mathbf{k}_\perp^2} \delta(1-x) . \end{aligned} \quad (81)$$

Similarly, we obtain for the advanced prescription:

$$f_1^{\text{adv}}(x, \mathbf{k}_\perp^2) = f_1^e(x, \mathbf{k}_\perp^2) + i \frac{e^2}{(2\pi)^2} \frac{1}{\mathbf{k}_\perp^2} \delta(1-x) . \quad (82)$$

In the principal value prescription, instead, the denominators of B and C remain unchanged because:

$$\frac{1}{2} \left[\frac{1}{p^+ + i\epsilon} + \frac{1}{p^+ - i\epsilon} \right] = \frac{1}{2} \left[\text{P.V.} \left(\frac{1}{p^+} \right) - i\pi \delta(p^+) + \text{P.V.} \left(\frac{1}{p^+} \right) + i\pi \delta(p^+) \right] \equiv \frac{1}{p^+}$$

and hence the final result coincides with the one found in Feynman gauge:

$$f_1^{\text{PV}}(x, \mathbf{k}_\perp^2) \equiv f_1^e(x, \mathbf{k}_\perp^2) . \quad (83)$$

We expect all results to be the same when adding also the transverse gauge link contribution. As we will show, the extra terms proportional to $\delta(1-x)$ in the retarded and advanced prescriptions are compensated by the contribution of the transverse gauge link, while the latter is vanishing in the principal value prescription. We remark that this is not what one finds usually in the case of the nucleon (see e.g. [12]), since the retarded prescription is the one corresponding to having $\mathbf{A}_\perp(\infty) = 0$ and hence the transverse gauge link should vanish in that prescription. However, we stress that in the present discussion we have not taken into account all the corrections to the distributions at the end-point $x = 1$, and this might explain the difference with the existing calculations in QCD.

We now turn to the evaluation of the transverse gauge link in the LFWF overlap representation. We start again with the integrated version of the correlator, with the states in the light-cone helicity basis:

$$\Phi(x, \mathbf{k}_\perp; \Lambda) := \int \frac{d\xi^- d^2 \xi_\perp}{(2\pi)^3} e^{ik \cdot \xi} \langle P, \Lambda | \bar{\psi}(0) \mathcal{U}_{(0,\infty)} \mathcal{U}_{(\infty,\xi)} \psi(\xi) | P, \Lambda \rangle \Big|_{\xi^+=0} . \quad (84)$$

We express the Wilson line in the light-cone gauge, using (10) approximated according to:

$$\mathcal{U}_{(0,\infty)} \mathcal{U}_{(\infty,\xi)} \simeq \mathbb{1} + ie \int_{\mathbf{0}_\perp}^{\xi_\perp} d\boldsymbol{\eta}_\perp \cdot \mathbf{A}_\perp(0, \boldsymbol{\eta}_\perp, \infty) = \mathbb{1} + ie \int_0^1 dt \mathbf{A}_\perp(0, t\boldsymbol{\xi}_\perp, \infty) \cdot \boldsymbol{\xi}_\perp . \quad (85)$$

We neglect the identity in (85) and we focus on the gauge-link terms. If we switch again to light-cone quantization and replace the dressed electron state $|P, \Lambda\rangle$ according to (47), in principle we will get four different combinations of states to consider. However, the term containing the gauge link between two $|e\gamma\rangle$ states is vanishing, because the

photon coming from the final (or initial) state interaction cannot couple to the spectator photon. The only relevant contributions will then come from the terms where the matrix element is between the states $|e\rangle$ and $|e\gamma\rangle$; in this situation, the gauge photon which interacts with the bare particle in the initial (or final) state coincides with the photon in the dressed electron. Therefore, we are left with the following two terms, contributing to the correlator:

$$I := \frac{ie}{2} \int \frac{d\xi^- d^2 \xi_\perp}{(2\pi)^3} e^{ik \cdot \xi} \langle e | \bar{\psi}(0) \left(\int_0^1 dt \mathbf{A}_\perp(0, t \xi_\perp, \infty) \cdot \xi_\perp \right) \psi(0) | e\gamma \rangle \Big|_{\xi^+=0}, \quad (86)$$

$$II := ie \int \frac{d\xi^- d^2 \xi_\perp}{(2\pi)^3} e^{ik \cdot \xi} \langle e\gamma | \bar{\psi}(0) \left(\int_0^1 dt \mathbf{A}_\perp(0, t \xi_\perp, \infty) \cdot \xi_\perp \right) \psi(0) | e \rangle \Big|_{\xi^+=0}. \quad (87)$$

Let us now restrict to the case of the TMD f_1^e ; we will begin with the evaluation of I . After some manipulations and resolving the integral over t , it can be split into two terms, $I = I_A + I_B$, with:

$$I_A := -\frac{e}{2} \int \frac{d\xi^- d^2 \xi_\perp}{(2\pi)^3} \int \frac{dx' d^2 \mathbf{k}'_\perp}{2(2\pi)^3 \sqrt{x'(1-x')}} e^{ik \cdot \xi} e^{-ip_e \cdot \xi} e^{-ip_\gamma^+ \infty} \times \sum_{\Lambda, \lambda, \lambda_\gamma} \frac{\varepsilon_{\perp \lambda_\gamma}(\mathbf{p}_\gamma) \cdot \xi_\perp}{\mathbf{p}_{\gamma \perp} \cdot \xi_\perp} \bar{u}_\Lambda(\mathbf{P}) \gamma^+ u_\lambda(\mathbf{p}_e) \Psi_{\lambda, \lambda_\gamma}^\Lambda(x', \mathbf{k}'_\perp) \Big|_{\xi^+=0}, \quad (88)$$

$$I_B := \frac{e}{2} \int \frac{d\xi^- d^2 \xi_\perp}{(2\pi)^3} \int \frac{dx' d^2 \mathbf{k}'_\perp}{2(2\pi)^3 \sqrt{x'(1-x')}} e^{ik \cdot \xi} e^{-ip_e \cdot \xi} e^{-ip_\gamma^+ \infty} e^{i \xi_\perp \cdot \mathbf{p}_{\gamma \perp}} \times \sum_{\Lambda, \lambda, \lambda_\gamma} \frac{\varepsilon_{\perp \lambda_\gamma}(\mathbf{p}_\gamma) \cdot \xi_\perp}{\mathbf{p}_{\gamma \perp} \cdot \xi_\perp} \bar{u}_\Lambda(\mathbf{P}) \gamma^+ u_\lambda(\mathbf{p}_e) \Psi_{\lambda, \lambda_\gamma}^\Lambda(x', \mathbf{k}'_\perp) \Big|_{\xi^+=0}, \quad (89)$$

where $\mathbf{p}_e = (x'P^+, \mathbf{k}'_\perp)$ and $\mathbf{p}_\gamma = ((1-x')P^+, -\mathbf{k}'_\perp)$. The sum appearing both in I_A and I_B is:

$$T := \sum_{\Lambda, \lambda, \lambda_\gamma} \bar{u}_\Lambda(\mathbf{P}) \gamma^+ u_\lambda(\mathbf{p}_e) \bar{u}_\lambda(\mathbf{p}_e) \gamma_\mu u_\Lambda(\mathbf{P}) \varepsilon_{\lambda_\gamma}^{\mu*}(\mathbf{p}_\gamma) \varepsilon_{\perp \lambda_\gamma}(\mathbf{p}_\gamma) \cdot \xi_\perp = -4P^+ \mathbf{p}_{e\perp} \cdot \xi_\perp \left(1 - 2 \frac{p_e^+}{p_\gamma^+} \right), \quad (90)$$

where we used the explicit expression of the LFWFs in terms of the spinors and polarization vectors. Equation (88) consequently becomes:

$$I_A = -2eP^+ \int \frac{d\xi^- d^2 \xi_\perp}{2(2\pi)^3} \int \frac{dx' d^2 \mathbf{k}'_\perp}{2(2\pi)^3 \sqrt{x'(1-x')}} e^{ik \cdot \xi} e^{-ip_e \cdot \xi} \left(-e^{-i\infty p_\gamma^+} + 2x'P^+ \frac{e^{-i\infty p_\gamma^+}}{p_\gamma^+} \right) \varphi(x', \mathbf{k}'_\perp) \Big|_{\xi^+=0}. \quad (91)$$

We isolated the term in brackets in the above equation because we need to specify how to handle the exponential at infinity [12, 13]: in the sense of principal value distribution, we can write:

$$\frac{e^{-i\infty p_\gamma^+}}{p_\gamma^+} \equiv \lim_{L \rightarrow \infty} \frac{e^{-iLp_\gamma^+}}{p_\gamma^+} = 2\pi i \chi \delta(p_\gamma^+), \quad (92)$$

where χ is a constant that takes different values, according to the prescription that we adopt for the denominator:

$$\chi = \begin{cases} -1 & \text{Retarded,} \\ 0 & \text{Advanced,} \\ -\frac{1}{2} & \text{Principal value.} \end{cases} \quad (93)$$

Again in the sense of principal value distribution, instead, we have:

$$e^{-i\infty p_\gamma^+} = 0, \quad (94)$$

which allows us to drop the first term in the bracket of (91). This is not surprising, because that term comes from the $-g^{\mu\nu}$ in the polarization sum, which appears in Feynman gauge also; then, this is consistent with the fact that the transverse gauge link does not contribute in the Feynman gauge.

Now we can easily perform the integration over ξ^- , ξ_\perp^2 , and then over x' , \mathbf{k}'_\perp , to arrive at:

$$I_A = -\frac{i\chi e^2}{(2\pi)^2} \frac{xP^+}{[(1-x)M^2 + \mathbf{k}_\perp^2]} \delta(p_\gamma^+) . \quad (95)$$

As for term I_B , which is now:

$$I_B = -eP^{+2} \int \frac{d\xi^- d^2\xi_\perp}{(2\pi)^3} \int \frac{dx' d^2\mathbf{k}'_\perp}{(2\pi)^3 \sqrt{x'(1-x')}} e^{ik \cdot \xi} e^{-ip_e \cdot \xi} \frac{e^{-i\infty p_\gamma^+}}{p_\gamma^+} x' \varphi(x', \mathbf{k}_\perp'^2) \Big|_{\xi^+=0} , \quad (96)$$

we notice that in any prescription (except for the advanced, where it is vanishing), it would become proportional to $\delta(1-x)$, thanks to (92); furthermore, the integration over ξ_\perp^2 would now bring a $\delta^{(2)}(\mathbf{k}_\perp)$. Then, we can conclude that this term would be relevant only in the end-point $\mathbf{k}_\perp = \mathbf{0}_\perp$, $x = 1$ and for this reason we will not consider it, consistently with what we did previously in the Feynman gauge.

A similar argument can be applied to the term II . It can in turn be split into the sum of two contributions, of which the first one becomes relevant only at the end-point, while the second one reads:

$$II_A = -\frac{eP^+}{(2\pi)^3} \int dx' \frac{x'}{\sqrt{x'(1-x')}} \frac{e^{i\infty p_\gamma^+}}{p_\gamma^+} \varphi(x', \mathbf{k}_\perp^2) \delta(1-x) . \quad (97)$$

In the sense of principal value distribution, also in the above equation we can write:

$$\frac{e^{i\infty p_\gamma^+}}{p_\gamma^+} = 2\pi i \zeta \delta(p_\gamma^+) , \quad (98)$$

where in this case, according to the different prescriptions, the constant ζ takes the values:

$$\zeta = \begin{cases} 0 & \text{Retarded ,} \\ 1 & \text{Advanced ,} \\ \frac{1}{2} & \text{Principal value .} \end{cases} \quad (99)$$

We now need to fix a prescription in order to proceed further. In the retarded prescription II_A is vanishing, while I_A becomes, from (95):

$$I_A = \frac{ie^2}{(2\pi)^2} \frac{xP^+}{[(1-x)M^2 + \mathbf{k}_\perp^2]} \frac{\delta(1-x)}{P^+} \equiv \frac{ie^2}{(2\pi)^2} \frac{1}{\mathbf{k}_\perp^2} \delta(1-x) . \quad (100)$$

If we fixed the advanced prescription, instead, we would find that I_A is zero, while II_A would read:

$$II_A = \frac{-ieP^+}{(2\pi)^2} \int dx' \frac{x'}{[(1-x')^2 M^2 + \mathbf{k}_\perp^2]} \frac{\delta(1-x')}{P^+} \delta(1-x) = -\frac{ie}{(2\pi)^2} \frac{1}{\mathbf{k}_\perp^2} \delta(1-x) . \quad (101)$$

In the principal value prescription, instead, the sum of I_A and II_A gives zero.

We may summarize our results by stating that the contribution of the transverse gauge link to the TMD $f_1^e(x, \mathbf{k}_\perp^2)$, in the different prescriptions, is:

$$\begin{aligned} \text{Retarded:} & \quad \frac{ie^2}{(2\pi)^2} \frac{1}{\mathbf{k}_\perp^2} \delta(1-x) , \\ \text{Advanced:} & \quad -\frac{ie^2}{(2\pi)^2} \frac{1}{\mathbf{k}_\perp^2} \delta(1-x) , \\ \text{Principal value:} & \quad 0 . \end{aligned} \quad (102)$$

Adding the contributions in (102) to the results (81), (82) and (83) in the corresponding prescriptions, we can see that the transverse gauge link allows one to compensate for the extra-terms that come from specific choices of a prescription for the regularization of the pole in the polarization sum, thus recovering the results obtained in the Feynman gauge. Similar results can be derived also for the other TMDs. We conclude that the transverse gauge link makes the evaluation of TMDs prescription-independent in the light-cone gauge.

FIG. 7: Handbag diagrams related to the TMDs of the photon.

VI. PHOTON TMDS

We now focus on the derivation of the TMDs for the photon inside the dressed electron. We still consider the scattering of the electron off a lepton, with the situation this time described by the handbag diagram in Fig. 7. We will now indicate with $k = (xP^+, k^-, \mathbf{k}_\perp)$ the four-momentum carried by the photon. In analogy with gluon TMDs in the QCD case [47–50], the relevant correlator between initial and final electron states for photon TMDs is⁵

$$\Phi^{\gamma[ij]}(k; P, S) := \frac{1}{xP^+} \int \frac{d\xi^- d^2\xi_\perp}{(2\pi)^3} e^{ik \cdot \xi} \langle P, S | F^{+j}(0) \mathcal{U}_{(0, \xi)} F^{+i}(\xi) | P, S \rangle \Big|_{\xi^+ = 0}. \quad (103)$$

The field tensor $F^{\mu\nu}$ in QED is already invariant under the gauge transformation (5), therefore in this case a Wilson line is not required. The situation is different in QCD, where the field tensor is not gauge invariant and gluon self-interactions are present.

If we introduce the symmetry operator $\hat{\mathbf{S}}$, whose action on an operator O^{ij} is defined by:

$$\hat{\mathbf{S}} O^{ij} = \frac{1}{2} \left(O^{ij} + O^{ji} - \delta_{i,j} \sum_m O^{mm} \right), \quad (104)$$

we have the following decomposition of the correlator (103) in terms of the leading-twist TMDs of a photon inside the dressed electron, which are obviously functions of (x, \mathbf{k}_\perp) [49]:

$$\sum_{i=1}^2 \Phi^{\gamma[ii]}(x, \mathbf{k}_\perp; S) = f_1^\gamma - \frac{\epsilon_\perp^{ij} k_\perp^i S_\perp^j}{m} f_{1T}^{\perp\gamma}, \quad (105)$$

$$i\epsilon_\perp^{ij} \Phi^{\gamma[ij]}(x, \mathbf{k}_\perp; S) = S_z g_{1L}^\gamma + \frac{\mathbf{k}_\perp \cdot \mathbf{S}_\perp}{m} g_{1T}^\gamma, \quad (106)$$

$$\begin{aligned} -\hat{\mathbf{S}} \Phi^{\gamma[ij]}(x, \mathbf{k}_\perp; S) = & -\frac{\hat{\mathbf{S}} k_\perp^i k_\perp^j}{2m^2} h_1^{\perp\gamma} + S_z \frac{\hat{\mathbf{S}} k_\perp^i \epsilon_\perp^{jk} k_\perp^k}{2m^2} h_{1L}^{\perp\gamma} + \frac{\hat{\mathbf{S}} k_\perp^i \epsilon_\perp^{jk} S_\perp^k}{2m} \left(h_{1T}^\gamma + \frac{\mathbf{k}_\perp^2}{2m^2} h_{1T}^{\perp\gamma} \right) \\ & + \frac{\hat{\mathbf{S}} k_\perp^i \epsilon_\perp^{jk} (2k_\perp^k \mathbf{k}_\perp \cdot \mathbf{S}_\perp - S_\perp^k \mathbf{k}_\perp^2)}{4m^3} h_{1T}^{\perp\gamma}, \end{aligned} \quad (107)$$

where the antisymmetric tensor ϵ_\perp^{ij} was defined in (14). For the photon TMDs we adopt the nomenclature of Ref. [49]: the letters f , g and h refer to the photon being unpolarized, circularly polarized or linearly polarized, respectively, while L and T still refer to the dressed electron being longitudinally or transversely polarized. Out of the eight photon TMDs implicitly defined in equations (105)-(107), four are T-even ($f_1^\gamma, g_{1L}^\gamma, g_{1T}^\gamma$ and $h_1^{\perp\gamma}$) and four T-odd ($f_{1T}^{\perp\gamma}, h_{1L}^{\perp\gamma}, h_{1T}^\gamma$ and $h_{1T}^{\perp\gamma}$).

If we work in the light-cone gauge, the components of the field tensor entering the correlator (103) reduce to $F^{+i} = \partial^+ A^i$. If we also switch to the light-cone helicity basis and apply the LFWF overlap representation method,

⁵ Indices i and j here refer to transverse Lorentz components.

we come up with:

$$\Phi^{\gamma[ij]}(x, \mathbf{k}_\perp, \Lambda) = \frac{1}{2(2\pi)^3} \sum_{\lambda, \lambda_\gamma, \lambda'_\gamma} \Psi_{\lambda, \lambda'_\gamma}^{\Lambda*}((1-x), -\mathbf{k}_\perp) \Psi_{\lambda, \lambda_\gamma}^\Lambda((1-x), -\mathbf{k}_\perp) \varepsilon_{\lambda'_\gamma}^{j*}(k) \varepsilon_{\lambda_\gamma}^i(k). \quad (108)$$

Further development of (108) yields⁶

$$\Phi^{\gamma[ij]}(x, \mathbf{k}_\perp, \Lambda) = \frac{|\varphi((1-x), \mathbf{k}_\perp^2)|^2}{2(2\pi)^3} \bar{u}_\Lambda(\mathbf{P}) \left(-\gamma^j + \frac{k_\perp^j}{xP^+} \gamma^+ \right) (\not{p}_e + m) \left(-\gamma^i + \frac{k_\perp^i}{xP^+} \gamma^+ \right) u_\Lambda(\mathbf{P}), \quad (109)$$

where the momentum of the inner electron is now $\mathbf{p}_e = ((1-x)P^+, -\mathbf{k}_\perp)$. The Feynman gauge result is completely equivalent, the difference in the polarization vectors being compensated by the extra $\partial_i A^+$ term in the field tensor.

If one takes the proper combinations of helicities for the dressed electron and transverse indices, it is easy to recover from equations (105)-(107) the following results for the leading twist photon TMDs:

$$f_1^\gamma(x, \mathbf{k}_\perp^2) = \frac{e^2}{(2\pi)^3} \frac{\mathbf{k}_\perp^2 [1 + (1-x)^2] + m^2 x^4}{x [\mathbf{k}_\perp^2 + m^2 x^2]^2}, \quad (110)$$

$$g_{1L}^\gamma(x, \mathbf{k}_\perp^2) = \frac{e^2}{(2\pi)^3} \frac{\mathbf{k}_\perp^2 (2-x) + m^2 x^3}{[\mathbf{k}_\perp^2 + m^2 x^2]^2}, \quad (111)$$

$$g_{1T}^\gamma(x, \mathbf{k}_\perp^2) = -\frac{2e^2}{(2\pi)^3} m^2 \frac{x(1-x)}{[\mathbf{k}_\perp^2 + m^2 x^2]^2}, \quad (112)$$

$$h_1^{\perp\gamma}(x, \mathbf{k}_\perp^2) = \frac{2e^2}{(2\pi)^3} m^2 \frac{(1-x)}{x [\mathbf{k}_\perp^2 + m^2 x^2]^2}, \quad (113)$$

$$f_{1T}^{\perp\gamma}(x, \mathbf{k}_\perp^2) = h_{1L}^{\perp\gamma}(x, \mathbf{k}_\perp^2) = h_{1T}^{\perp\gamma}(x, \mathbf{k}_\perp^2) = h_{1T}^\gamma(x, \mathbf{k}_\perp^2) = 0. \quad (114)$$

Notice that the T-odd functions are vanishing: this is not surprising, since there are no contributions that can be interpreted as final state interactions. Even if we go up to order α^2 , we checked that T-odd TMDs still vanish. This is probably true to all orders, since it is related to the absence of a gauge link in the correlator. The vanishing of the Sivers function up to order α^2 is also consistent with the sum rule derived by Burkardt [48, 51, 52], since we found that the Sivers effect for the electron vanishes both at order α and α^2 .

VII. NUMERICAL RESULTS

In this section we discuss the numerical results for the electron TMDs. In Fig. 8, we present the unpolarized TMD f_1^e (upper left panel), and the TMD g_{1L}^e (upper right panel) for longitudinally polarized electrons in a longitudinally polarized electron, as functions of \mathbf{k}_\perp^2 and for different values of x . In the lower panels of Fig. 8, we show the corresponding results for the combinations $f^{+e} = (f_1^e + g_{1L}^e)/2$ and $f^{-e} = (f_1^e - g_{1L}^e)/2$, describing the probability to find the internal electron with spin aligned and anti-aligned to the spin of the parent electron, respectively. As discussed in Sec. IV A, f_1^e and g_{1L}^e are given by different combinations of the squares of S- and P-wave components. In particular, f_1^e is obtained from the sum of the contribution from the two partial-waves, while in g_{1L}^e one has the difference between the S- and P-wave contributions. Correspondingly, with the combination f^{+e} we isolate the contribution from P waves to both f_1^e and g_{1L}^e , while f^{-e} gives the S-wave contribution which enters with a positive sign in f_1^e and a negative sign in g_{1L}^e . We notice that for $\mathbf{k}_\perp^2 \rightarrow 0$, the P-wave contribution is vanishing, while the S-wave contribution reaches its maximum, with larger values at increasing x . On the other side, the fall-off in \mathbf{k}_\perp^2 of the S-wave contribution is very steep, and the contribution of the P-wave takes over at increasing transverse momentum. This also means that, for vanishing transverse momentum, the configuration with the spin of the internal electron being anti-aligned with the spin of the target electron and the spin of the photon being aligned with the spin of the

⁶ Notice that the denominator from the photon propagator does not need to be regularized, since we are not integrating over the photon momentum.

target electron is favored, and at larger k_\perp^2 the spin of the internal electron is most likely to flip in the direction of the spin of the parent electron. The spin-flip of the active parton at low transverse momentum is also responsible for the sign change in g_{1L}^e , which occurs faster in k_\perp^2 at larger values of x .

In Fig. 9 we show the results for the transversity TMD h_1^e , and the combinations $h^{+e} = (f_1^e + h_1^e)/2$ and $h^{-e} = (f_1^e - h_1^e)/2$, describing the probability of finding the internal electron with transverse spin aligned and anti-aligned to the transverse spin of the parent electron, respectively. Being chiral odd, h_1^e involves an helicity-flip of the internal electron from the initial to the final state, which is compensated by a helicity-flip of the parent electron in same direction. Since total helicity is the same in initial and final states, h_1^e is diagonal in OAM, and, from the LFWF overlap representation in Eq. (70), we note that it is given in terms of the partial waves with $L_z = \pm 1$ only, without contributions from the S-wave components. The P-waves enter in h_1^e with different combinations with respect to the contribution in f_1^e and g_{1L}^e , as given by f^{+e} . In particular, from the LFWF overlap representation in Eqs. (65), (66), and (70), we find that f^{+e} contains the sum of the square of the $L_z = +1$ and $L_z = -1$ components, while h_1^e is given by the interference between the two P-waves, i.e.

$$f^{+e}(x, \mathbf{k}_\perp^2) = \frac{1}{2(2\pi)^3} [|\Psi_{+,+1}^+(x, \mathbf{k}_\perp)|^2 + |\Psi_{+,-1}^+(x, \mathbf{k}_\perp)|^2] , \quad (115)$$

$$h_1^e(x, \mathbf{k}_\perp^2) = \frac{1}{(2\pi)^3} \text{Re} \left[\Psi_{+,+1}^{+*}(x, \mathbf{k}_\perp) \Psi_{+,-1}^-(x, \mathbf{k}_\perp) \right] , \quad (116)$$

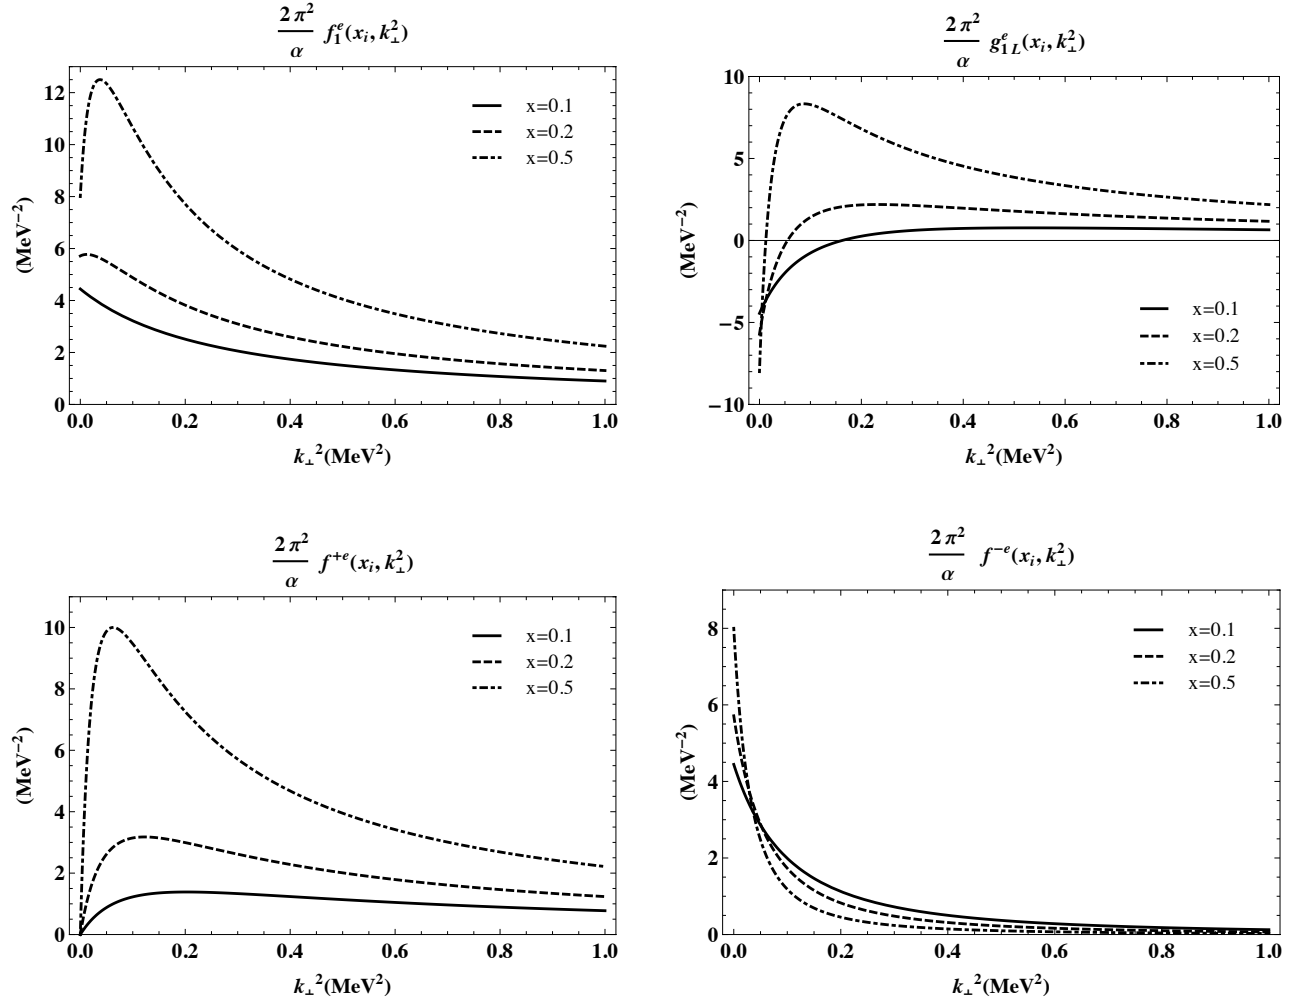

FIG. 8: TMDs $f_1^e(x, \mathbf{k}_\perp^2)$ (upper left panel), $g_{1L}^e(x, \mathbf{k}_\perp^2)$ (upper right panel), along with their sum (lower left panel) and their difference (lower right panel). All distributions are rescaled by a factor $2\pi^2/\alpha$, and shown as function of k_\perp^2 , and for different values of the longitudinal momentum fraction x : $x = 0.1$ (solid curves); $x = 0.2$ (dashed curves), and $x = 0.5$ (dashed-dotted curves).

FIG. 9: TMDs $h_1^e(x, \mathbf{k}_\perp^2)$ (upper panel), $h_1^{+e}(x, \mathbf{k}_\perp^2)$ (lower left panel) and $h_1^{-e}(x, \mathbf{k}_\perp^2)$ (lower right panel), rescaled by a factor $2\pi^2/\alpha$, as function of \mathbf{k}_\perp^2 , and for different values of the longitudinal momentum fraction x : $x = 0.1$ (solid curves); $x = 0.2$ (dashed curves), and $x = 0.5$ (dashed-dotted curves).

where we used the property (60) of the two-body component of the electron LFWFs. From the analytical expressions in Eqs. (38), (39) and (43), one also finds

$$h_1^e(x, \mathbf{k}_\perp^2) = \frac{2x}{1+x^2} f^{+e}(x, \mathbf{k}_\perp^2). \quad (117)$$

As a result, h_1^e has the same dependence on \mathbf{k}_\perp^2 as f^{+e} , but its overall size is always smaller, particularly at smaller values of x . In the combination h^{+e} , the positive contribution from the S-wave components of f_1^e is evident at vanishing transverse momentum, while at higher values of \mathbf{k}_\perp^2 the contributions of the P-waves from f_1^e and h_1^e become dominant. In the case of h^{-e} the P-waves contributions from f_1^e and h_1^e partially cancel, especially at higher values of x , and we find that the low \mathbf{k}_\perp^2 behavior is dominated from the S-wave contribution of f_1^e , while the P-waves still control the tail at higher transverse momentum. As a consequence, at $x = 0.5$ the transverse spin of the internal electron tends to be aligned with the transverse spin of the parent electron in the full \mathbf{k}_\perp^2 range, while for smaller values of x there is no marked preference between the parallel or antiparallel configuration of the two transverse spins.

In Fig. 10 we show the TMD g_{1T}^e for longitudinally polarized electrons in a transversely polarized electron target in comparison with $h_{1L}^{\perp e}$, describing the momentum distribution for transversely polarized electron in a longitudinally polarized electron target. These distributions are characteristic effects due to transverse momentum, since they are the only ones which have no analog in the spin densities related to the GPDs in the impact parameter space [53], and vanish after integration over \mathbf{k}_\perp . Since the LFWFs $\Psi_{-, -1}^+$ and $\Psi_{+, +1}^-$ vanish, the LFWF overlap representation in

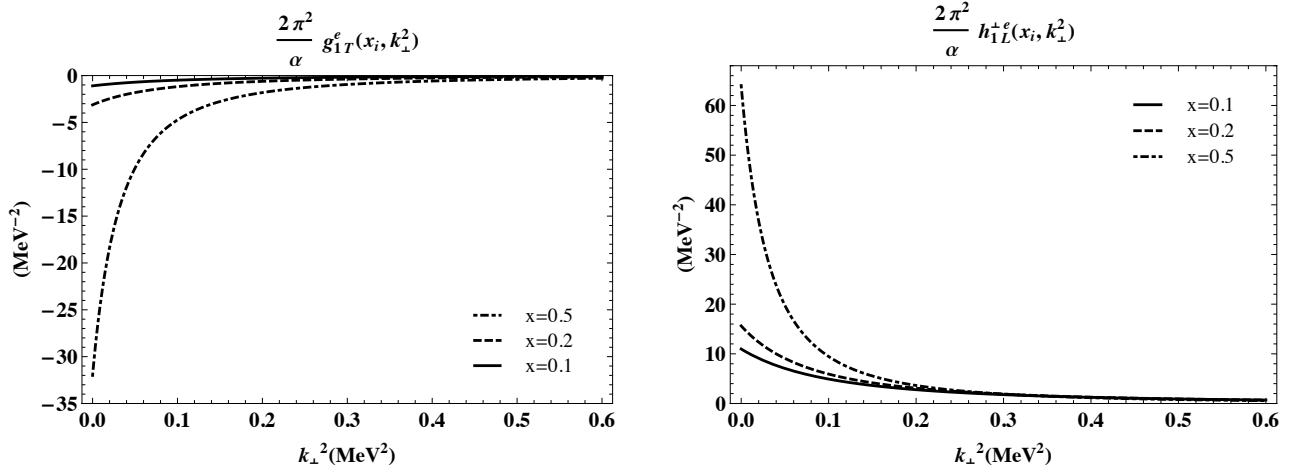

FIG. 10: TMDs $g_{1T}^e(x, \mathbf{k}_\perp^2)$ (left panel), $h_{1L}^e(x, \mathbf{k}_\perp^2)$ (right panel), rescaled by a factor $2\pi^2/\alpha$, as function of \mathbf{k}_\perp^2 , and for different values of the longitudinal momentum fraction x : $x=0.1$ (solid curves); $x=0.2$ (dashed curves), and $x=0.5$ (dashed-dotted curves).

Eqs. (67) and (68) can be rewritten as

$$g_{1T}^e(x, \mathbf{k}_\perp^2) = \frac{m}{2(2\pi)^3 \mathbf{k}_\perp^2} \text{Re} \left[k_R \Psi_{+,-1}^{+*}(x, \mathbf{k}_\perp) \Psi_{+,-1}^-(x, \mathbf{k}_\perp) \right], \quad (118)$$

$$h_{1L}^e(x, \mathbf{k}_\perp^2) = \frac{m}{(2\pi)^3 \mathbf{k}_\perp^2} \text{Re} \left[k_R \Psi_{-,+1}^{+*}(x, \mathbf{k}_\perp) \Psi_{+,+1}^+(x, \mathbf{k}_\perp) \right]. \quad (119)$$

We notice that g_{1T}^e requires helicity flip of the electron target that is not compensated by a change of the helicity of the internal electron, and vice-versa h_{1L}^e involves helicity flip of the internal electron, but is diagonal in the helicity of the electron target. As a result, the two distributions require a transfer of OAM between the initial and final state: in the case of g_{1T}^e , this comes from the interference of the S-wave and the P-wave with $L_z = +1$, while for h_{1L}^e is driven from the S-wave and the P-wave with $L_z = -1$. The difference between the two P-waves in Eqs. (52) and (53) leads to the following relations for the TMDs

$$g_{1T}^e(x, \mathbf{k}_\perp^2) = -x h_{1L}^e(x, \mathbf{k}_\perp^2), \quad (120)$$

which explains the suppression of g_{1T}^e , in absolute value, with respect to h_{1L}^e , especially at lower value of x .

From Eqs. (17)-(19) and omitting the contributions of f_{1T}^e , h_{1T}^e and h_{1L}^e , which are vanishing at leading order in α , we can form the following densities for electrons of definite longitudinal or transverse polarization

$$\rho(x, k_x, k_y, (\lambda, \mathbf{s}_\perp), (\Lambda, \mathbf{S}_\perp)) = \frac{1}{2} \left[f_1^e + \lambda \Lambda g_{1L}^e + \lambda S_\perp^i k_\perp^i \frac{1}{m} g_{1T}^e + \Lambda s_\perp^i k_\perp^i \frac{1}{m} h_{1L}^e + s_\perp^i S_\perp^i h_1^e \right], \quad (121)$$

where we denoted the transverse spin of the internal electron with s_\perp .

In Fig. 11 we show the densities in the transverse momentum plane and at fixed $x = 0.5$ for longitudinally polarized electron target and longitudinally polarized internal electron, with helicity in the same (f^{+e}) or opposite (f^{-e}) direction, along with the corresponding results for f_1^e . As discussed above, the behavior of f^{+e} is determined from the P-waves, which rapidly increase starting from the dip in the centre, reach a maximum at $|\mathbf{k}_\perp| \approx 200$ keV and smoothly decrease at larger values. On the other hand, the S-wave contribution to f^{-e} is maximum at the centre and rapidly falls off towards the periphery of the $k_x - k_y$ plane. The interplay between the P- and S-wave contributions determines the pattern of $f_1^e = f^{+e} + f^{-e}$ from the centre to higher values of \mathbf{k}_\perp . In summary the density of electrons in a dressed electron in momentum space, averaged over all polarizations, at $x = 0.5$, looks like a ring-shaped image, with a radius of about 200 keV.

In Fig. 12 we show the transverse-polarization densities h^{+e} and h^{-e} . Qualitatively, they look similar to their longitudinal counterparts, but they are different in the details. The P-wave contribution is more pronounced in h^{+e} , but the S-wave is also present, and the density at $\mathbf{k}_\perp^2 = 0$ is not zero. The S-wave dominates in h^{-e} , but a P-wave contribution is also present, even though it is suppressed. Note that, in principle, the transverse-polarization density

FIG. 11: Density plots in the transverse momentum plane k_x-k_y and at fixed value of $x = 0.5$ for f^{+e} (upper left panel), f^{-e} (upper right panel) and f_1^e (lower panel), rescaled by a factor $2\pi^2/\alpha$. The legend in the bottom-right corner of each panel indicates the corresponding spin configurations: the grey and white empty discs refer to the unpolarized dressed and unpolarized bare electron, respectively; the circle and cross inside the discs stand for polarization along the longitudinal axes, in opposite directions.

could in principle be not cylindrically symmetric. However, the fact that $h_{1T}^{\perp e}$ and $h_{1L}^{\perp e}$ vanish in QED at this order makes the density symmetric.

In Fig. 13 the distorting effect induced by the polarization is shown. In the left panel, we present the density in the transverse momentum plane and at fixed $x = 0.5$ for longitudinally polarized electrons in an electron target transversely polarized along the y direction. This is obtained by adding the dipole deformation due to the term $\frac{k_y}{m} g_{1T}^e$ in Eq. (121) to the monopole distribution of f_1^e . The term in g_{1T}^e features a significant dipole deformation along the direction of the spin of the parent electron, and is responsible for the sizable downward shift along y . An analogous observation can be made for transversely polarized electrons in a longitudinally polarized electron target, as displayed in the right panel of Fig. 13. In this case, the effect of the distortion is even more pronounced and in the opposite direction, since the strength of the deformation is due to the term $\frac{k_y}{m} h_{1L}^{\perp e}$, with $h_{1L}^{\perp e} = -2g_{1T}^e$ at $x = 0.5$.

We avoid showing plots of all the photon TMDs, but we take the chance to make a few observations. The functions f_1^γ and g_{1T}^γ are similar to their electron counterparts with the replacement $x \leftrightarrow (1-x)$. The helicity distribution has no straightforward relation to the electron helicity distribution. At variance with the electron case, the combination $f^{-\gamma}$ contains contributions only from P waves, while $f^{+\gamma}$ contains contributions from both P and S waves. The other nonvanishing photon TMD is the so-called Boer-Mulders function $h_1^{\perp\gamma}$, describing linearly polarized photons

FIG. 12: Density plots in the transverse momentum plane $k_x - k_y$ and at fixed value of $x = 0.5$ for h^{+e} (left panel) and h^{-e} (right panel), rescaled by a factor $2\pi^2/\alpha$. The legend in the bottom-right corner of each panel indicates the corresponding spin configurations: the grey and white discs refer to the dressed and bare electron, respectively; the arrows indicate polarization along the y direction.

FIG. 13: Density plots in the transverse momentum plane $k_x - k_y$ and at fixed value of $x = 0.5$ for the sum $(f_1^e + \frac{k_y}{m} g_{1T}^e)/2$ (left panel) and $(f_1^e + \frac{k_y}{m} h_{1L}^e)/2$ (right panel), rescaled by a factor $2\pi^2/\alpha$. The legend in the bottom-right corner of each panel indicates the corresponding spin configurations: the grey and white discs refer to the dressed and bare electron, respectively; the circle inside the discs stands for polarization along the longitudinal axes; the arrows indicate polarization along the y direction.

in an unpolarized electron [47, 49, 54]. We plot it in Fig. 14 (left panel), where we observe that it is very large, especially at low x . The corresponding function for photons and gluons in a proton has been the topic of a few articles in the last years [55–57], mainly because it does not require polarized targets and it can be generated through perturbative QCD corrections [58], similarly to what happens in our QED calculation. In Fig. 14 (right panel), we plot the combination $(f_1^\gamma + (k_y^2 - k_x^2)/(2m^2)h_1^{\perp\gamma})/2$ corresponding to the density of photons with linear polarization along the y direction in an unpolarized dressed electron. The distribution has two peaks, shifted along the polarization direction by approximately ± 200 keV at $x = 0.5$.

FIG. 14: Left panel: photon TMD $h_1^{\perp\gamma}(x, \mathbf{k}_\perp^2)$, rescaled by a factor $2\pi^2/\alpha$, as function of \mathbf{k}_\perp^2 , and for different values of the longitudinal momentum fraction x : $x = 0.1$ (solid curves); $x = 0.2$ (dashed curves), and $x = 0.5$ (dashed-dotted curves). Right panel: density plot in the transverse momentum plane $k_x - k_y$ and at fixed value of $x = 0.5$ for the combination $(f_1^\gamma + (k_y^2 - k_x^2)/(2m^2)h_1^{\perp\gamma})/2$, rescaled by a factor $2\pi^2/\alpha$. The legend in the bottom-right corner of indicates the corresponding spin configurations: the grey empty disc refers to the unpolarized dressed electron, the white disc with arrow indicate a photon with linear polarization along the y direction.

VIII. CONCLUSIONS

In this article we analyzed the dressed electron at order α as a system effectively composed by an electron and a photon. In analogy with QCD parton distribution functions, we studied all twist-2 polarized transverse-momentum-dependent distribution functions (TMDs) of the electron and photon in the dressed electron, which describe the three-dimensional structure of the dressed electron in momentum space.

We performed the calculation of electron TMDs in Feynman gauge and light-cone gauge up to order α and for $x \neq 1$, $\mathbf{k}_\perp \neq \mathbf{0}_\perp$. We explicitly checked the equivalence of the two gauges, and the critical role played by Wilson lines in the gauge-invariant definition of TMDs. This result was already known for the QCD case, but the explicit QED calculation is particularly useful for illustration purposes. A nontrivial question concerns the contributions of transverse Wilson lines, which in our QED calculation at order α appear only at the endpoint $x = 1$. In this case, we showed how the choice of different prescriptions for the photon propagator is correctly compensated by the contribution of transverse Wilson lines.

In light-cone gauge, we performed the calculation of TMDs in two different approaches, namely using Feynman diagrams and using the overlap representation in terms of light-front wave functions (LFWFs), confirming the equivalence of the two approaches.

We calculated photon TMDs using their gauge-invariant definition which, in the QED case, does not require the addition of Wilson lines. The results are in fact the same for Feynman gauge and light-cone gauge.

The results of the electron TMDs are summarized in Eqs. (38) to (44). T-odd TMDs ($h_1^{\perp e}$ and $f_{1T}^{\perp e}$) are zero, a result that holds true also at order α^2 due to the lack of contributing diagrams. Also the T-even TMD $h_{1T}^{\perp e}$ vanishes in QED at order α .

The results of the photon TMDs are summarized in Eqs. (110) to (114). All T-odd TMDs ($f_{1T}^{\perp\gamma}$, $h_{1L}^{\perp\gamma}$, $h_{1T}^{\perp\gamma}$, h_{1T}^{γ}) are zero. We checked that this is true also at order α^2 and we argued that is probably true at any order α^n .

In the last part of the article, we showed several plots that visualize TMDs in various ways, including multi-dimensional density plots of the structure of the dressed electron in momentum space. For instance, we showed that the density of electrons (and photons, by symmetry) in a dressed electron in momentum space, averaged over all polarizations, at $x = 0.5$, looks like a ring-shaped image, with a radius of about 200 keV.

We observed that the inclusion of polarization causes several interesting effects. Different combinations of longitudinal polarizations make it possible to isolate contributions with different projections of orbital angular momentum. Some polarized distributions are not cylindrically symmetric. For instance, the density of linearly polarized photons inside the dressed electron (related to the TMD $h_1^{\perp\gamma}$) has a distribution with two peaks, shifted along the polarization

direction by approximately ± 200 keV at $x = 0.5$. The shifts increase towards lower x . Transverse polarization of the dressed electron causes distortions in the density distributions of longitudinally polarized electrons, with shifts of the order of 200 keV at $x = 0.5$, decreasing towards lower x .

Our analysis can be further extended by including the contributions from the endpoints and the treatment of infrared and rapidity divergences. Another possible direction of study would be to identify which observables are sensitive to the TMDs of a dressed electron.
